Fig. 33.9 Clostridial myonecrosis (gas gangrene). (From Finegold, S. M., et al. [1986]. Anaerobic infections. Kalamazoo, MI: Upjohn.)

With certain organisms (e.g., *S. pyogenes*, *S. aureus*, or *Clostridium* spp.), the pathophysiology of necrotizing infection involves toxin production and induction of inflammatory cytokines leading not only to extensive soft tissue damage but also systemic effects like shock and multiorgan failure. Toxic shock syndrome may occur in the setting of necrotizing infection caused by *S. pyogenes* or *S. aureus* (see the "Toxic Shock Syndrome" section later in this chapter).

Initially, pain at the involved site is out of proportion to the physical findings. Hemorrhage and necrosis of the skin ensue, with formation of bullae and palpable gas (crepitus) caused by tissue ischemia from thrombosed blood vessels. Loss of sensation of the involved area of skin and soft tissue may occur. Certain laboratory findings can support the diagnosis of necrotizing fasciitis; the white blood cell count is often more than $15 \times 10^9/L$, and there may be increased levels of C-reactive protein, lactate, creatinine kinase, creatinine, and glucose and decreased levels of serum sodium or hemoglobin. Necrotizing soft tissue infection often progresses from superficial to deep tissue involvement in a rapid manner, risking limb loss, systemic toxicity, and death.

Gangrenous soft tissue infections represent true medical and surgical emergencies. Immediate surgical exploration is required to determine the degree and level of soft tissue spread, excise all devitalized tissue, and obtain deep tissue specimens for Gram stain and bacterial cultures. Blood cultures may also be positive. Early surgical debridement is the major determinant of patient survival. However, before surgical exploration and debridement, combination antimicrobial therapy should be initiated and should include vancomycin or daptomycin plus piperacillin-tazobactam or a carbapenem.

Case check 33.2

Skin infections in diabetic persons may evolve into the rapidly progressive type I necrotizing fasciitis, in which infection extends through the subcutaneous tissues to the fascia. Necrotizing soft tissue infections are associated with fever, leukocytosis, and shock, requiring emergent surgical debridement and antimicrobial therapy. Infections of this type are polymicrobial, caused by aerobic gram-positive organisms, including staphylococci and streptococci, as well as Enterobacteriales and anaerobic bacteria.

plus clindamycin, which can inhibit toxin production by streptococci and staphylococci. Empiric therapy should be active against aerobic gram-positive cocci including MRSA, Enterobacterales, and anaerobes to ensure adequate coverage.

Mycetoma

Mycetoma (also called *Madura foot* or *maduromycosis*) is a chronic skin and subcutaneous infection caused by either bacteria or fungi. It is known as *eumycetoma* or *true fungal infection* when caused by fungi, such as *Madurella* spp., *Aspergillus* spp., or *Pseudallescheria boydii*, and as *actinomycetoma* when caused by filamentous bacteria, including actinomycetes such as *Nocardia* or *Actinomadurea* spp. (Table 33.4).

Madura foot is characterized by localized swelling and abscess formation within subcutaneous tissues and the development of sinus tracts, with visible grains/granules that are 0.2 to 0.5 mm in size formed by aggregates of organisms in the pus draining from these fistulae (Fig. 33.10). The disease progresses slowly and is destructive, with extension to muscle and bone. Soil, plants, and decaying vegetation are reservoirs for the causative organisms. The disease is often seen in outdoor laborers and may be a result of lack of protective clothing, including shoes; it develops as a result of skin trauma with an object contaminated with fungal elements (e.g., thorns, splinters) or introduction of organisms into preexisting abrasions. There is no person-to-person transmission.

Table 33.4 Major causative agents of subcutaneous mycoses

Disease	Principal organism(s)
Eumycetoma	<i>Madurella</i> spp., <i>Blastosporium</i> spp., <i>Scedosporium apiospermum</i> complex, <i>Leptosphaeria senegalensis</i> , <i>Exophiala</i> spp., <i>Curvularia</i> spp., <i>Phialophora verrucosa</i> , <i>Pyrenochaeta romeroi</i> , <i>Fusarium</i> spp., <i>Acremonium</i> spp., <i>Pseudallescheria boydii</i> , <i>Aspergillus</i> spp., <i>Neotestudina rosatii</i> , <i>Pleurostomophora ochracea</i> , <i>Trematosphaeria grisea</i>
Actinomycetoma	<i>Actinomadurea madurae</i> , <i>Actinomadurea pelletieri</i> , <i>Nocardia</i> spp., <i>Streptomyces somaliensis</i>
Chromoblastomycosis	<i>Phialophora verrucosa</i> , <i>Fonsecaea pedrosoi</i> , <i>Fonsecaea compacta</i> , <i>Fonsecaea monophora</i> , <i>Cladophialophora carrionii</i> , <i>Rhinocladiella aquaspersa</i> , <i>Exophiala</i> spp.
Phaeohyphomycosis	Dematiaceous fungi (e.g., <i>Phialophora</i> , <i>Wangiella</i> , <i>Exophiala</i> , <i>Exserohilum</i> , <i>Alternaria</i> , <i>Cladosporium</i> , <i>Curvularia</i> , <i>Bipolaris</i>)
Sporotrichosis	<i>Sporothrix schenckii</i>
Rhinoentomophthoromycosis	<i>Conidiobolus</i> , <i>Basidiobolus</i>
Lobo disease	<i>Lacazia loboi</i> (<i>Loboia loboi</i>)

The foot is the most commonly affected site (70%) followed by the lower leg and hand. Other sites of infection can include the shoulder and back, with the face rarely involved. The infected sites are usually nontender, and no systemic signs of infection occur. Mycetoma is rare in the continental United States but common in tropical and subtropical regions of the world, especially where people walk barefoot. It is unclear whether there are specific genetic predispositions to mycetoma, but it is not seen in classically immunocompromised persons.

The diagnosis of mycetoma is usually made based on the clinical appearance and microscopic examination and culture of the grains. Aspiration of an area of soft tissue swelling for microscopy and culture can also be performed. Treatment with antimicrobials should be prolonged, and surgery to debulk the disease is often necessary. Amputation may be required for cure. Eumycetomas respond best to azole antifungal agents such as itraconazole, voriconazole, posaconazole, or isavuconazole. Actinomycetoma may be treated with trimethoprim-sulfamethoxazole and may sometimes require combination antimicrobial therapy with amikacin. Other agents that may have activity in the treatment of actinomycetoma include imipenem, minocycline, amoxicillin-clavulanate, linezolid, and the fluoroquinolones.

Mycetoma may be difficult to distinguish from chronic osteomyelitis and botryomycosis, the latter being a clinically and pathologically similar entity caused by a variety of bacteria, including staphylococci and gram-negative bacteria. Specific diagnosis depends on visualizing the granules in fresh preparations or histopathologic sections and isolating the causative actinomycete or fungus in culture. Different causative agents produce differently colored and sized granules, which can help in determining the etiologic organism.

Chromoblastomycosis

Chromoblastomycosis or chromomycosis is a chronic spreading mycosis of the skin and subcutaneous tissues. It produces localized wartlike, scaly lesions, usually of a lower extremity (Fig. 33.11) or, less commonly, the hand or back. The disease has been found worldwide but, like mycetoma, is most common in tropical and subtropical regions. The mode of transmission is also like that of mycetoma and occurs through skin inoculation of organisms via minor trauma. Progression is

Fig. 33.10 Madura foot. (Courtesy Dr. Gail Reid, Loyola University Medical Center, Maywood, IL.)

Fig. 33.11 Chromoblastomycosis of the leg. (Courtesy Dr. Gail Reid, Loyola University Medical Center, Maywood, IL.)

slow over a period of years, with eventual large cauliflower-like masses and obstruction of lymphatic drainage, in some cases leading to marked swelling of the affected site. Unlike mycetoma, chromoblastomycosis generally does not involve muscle or bone.

Infectious agents include the dark-walled (dematiaceous) fungi found in soil and decaying vegetation. *Fonsecaea pedrosoi* is usually isolated, although other potential pathogens include *F. monophora*, *F. compacta*, *Phialophora verrucosa*, *Cladophialophora carrionii*, and *Rhinocladiella aquaspersa*. Rare cases caused by *Exophiala* spp. have also been described, and the climate of a region may predispose to infection by a specific chromoblastomycosis agent. Microscopic examination of scrapings or biopsy specimens from lesions reveals characteristic brown, thick-walled, rounded cells known as *sclerotic* or *copper penny bodies* that divide by fusion in two planes. Confirmation of the diagnosis is made by biopsy and culture of the causative fungus on SDA, typically resulting in dark, pigmented colonies of fungus that may take weeks to grow. Excision of localized lesions provides optimal results. For more extensive skin involvement, a combined approach of antifungal agents such as itraconazole or terbinafine along with debridement where feasible and/or application of liquid nitrogen or heat may be effective. Voriconazole, posaconazole, and isavuconazole display in vitro activity against many of the agents of chromoblastomycosis.

Other uncommon fungi

The term **phaeohyphomycosis** refers to infections caused by fungi that produce dark cell walls. These fungi are also known as *dematiaceous*, again referring to their brown or black pigmentation. In addition to causing some cases of mycetoma and chromoblastomycosis, the agents of phaeohyphomycosis can cause subcutaneous nodules (as well as deeper infections such as brain abscess, septic arthritis, pneumonia, and sinusitis). *Curvularia* and the closely related genus *Bipolaris*, *Exophiala*, and *Phialophora* are some of the common genera isolated from skin lesions, although many others constitute this group. They are found in soil and decaying organic matter and on plants and are usually introduced into the body in a manner like mycetoma and chromoblastomycosis, through trauma and breaks in the skin.

Subcutaneous phaeohyphomycosis starts as an erythematous nodule, often on the extremities, at a site of minor trauma. The lesion typically enlarges and may involve deep tissues, including bone. The infection can spread locally with the formation of additional nodules. Immunocompromised persons are at highest risk for this infection, and in this setting the infection can disseminate to other regions of the body, including the brain. The diagnosis is made on biopsy and culture of a skin lesion, although the dark pigment of the organisms may not be easily visualized on hematoxylin and eosin tissue staining and may require staining by the Fontana-Masson method. Surgical debridement is generally necessary for cure; several antifungal agents are active against these organisms, including amphotericin B (usually reserved for life-threatening cases), itraconazole, voriconazole, and posaconazole.

Mucormycosis is an infection caused by fungi that belong to the order Mucorales. Mucorales organisms are ubiquitous in nature and have broad, irregular hyaline hyphae with rare septations. They may be found in food, vegetation, animal excreta, and soil. The disease resulting from these agents is termed *mucormycosis*. Within the order Mucorales, disease is caused most often by the genus *Rhizopus*, although *Mucor*, *Rhizomucor*, *Cunninghamella*, *Apophysomyces*, and *Lichtheimia* (formerly *Absidia* and *Myocladus*) are other common genera identified in human infections. Disease results less frequently from genera such as *Saksenaia* and *Syncephalastrum*.

Patients typically develop localized cutaneous mucormycosis via skin inoculation from trauma, including from burns, surgery, or IV drug use. Contaminated bandages and bed linens have also resulted in nosocomial outbreaks of skin and soft tissue mucormycosis. The more common mode of acquiring the infection is through inhalation of fungal spores from the environment. Ingestion is another route; the skin can then also be involved by dissemination from the lungs, sinuses, brain, or gastrointestinal (GI) tract (see the “Dermatologic Manifestations of Systemic Bacterial and Fungal Infections” section later in this chapter). Risk factors for infection include uncontrolled diabetes mellitus, leukemia, bone marrow and solid organ transplantation, corticosteroid therapy, and exposure to the iron chelator deferoxamine, which can make iron more available for use by the fungus. Disseminated mucormycosis has a high fatality rate.

Cutaneous lesions are often erythematous and develop black, necrotic areas. They can progress quickly. The diagnosis is made by biopsy of tissue for histologic examination and culture. The finding of irregular, aseptate hyphae branching at 90-degree angles suggestive of mucormycosis in the tissue of a diabetic or immunocompromised patient is a critical value, and the patient’s health care provider should be notified immediately. Mucorales often grow quickly on SDA, and morphologic features of fungal growth can allow genus identification. Matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry and polymerase chain reaction (PCR) are increasingly used for identification when fungi cannot be identified morphologically. The mainstay of treatment for mucormycosis is surgical debridement in combination with amphotericin B, although susceptibility to amphotericin B varies by species. Posaconazole and the newest triazole, isavuconazole, also have activity against Mucorales.

Fluconazole and voriconazole are not clinically useful, and echinocandins alone are not active against Mucorales.

Fungi of the order Entomophthorales are also present in organic debris and can cause **entomophthoromycosis**, a chronic subcutaneous form of infection. This is often the result of traumatic implantation of the organisms in the skin. Entomophthoromycosis is caused by organisms of two genera: *Conidiobolus* (*C. coronatus*, *C. incongruus*) and *Basidiobolus* (*B. ranarum*). Entomophthoromycosis is most often seen in tropical and subtropical regions, especially in Africa, Southeast Asia, and Latin America. *B. ranarum* causes subcutaneous infection of the limbs or trunk, particularly the shoulders, hips, thighs, and buttocks. It is characterized by nontender rubbery masses that can be large and ulcerate and is predominantly a disease of early childhood. *Conidiobolus* infection is localized to the facial area, typically in adults. *Conidiobolus* infections occur after inhalation of fungal spores that subsequently invade the sinuses and facial soft tissues and cause painless swelling of the lips and face that can be very deforming. Occasionally, these infections may spread to other areas of the body, particularly in immunocompromised persons.

Diagnosis can be made clinically based on the typical skin and soft tissue findings but should be confirmed with biopsy, which shows broad hyphae with few septations and surrounding eosinophils. Culture of tissue obtained from biopsy should also be performed but may be negative. *Conidiobolus* is less susceptible to antifungal therapy than *Basidiobolus* and may require debridement along with a combination of itraconazole and potassium iodide. Itraconazole is active against *Basidiobolus*. Limited data are available on the utility of newer triazoles, but posaconazole and voriconazole may have activity.

Lobomycosis is a chronic fungal infection of the skin caused by *Lacazia loboi* (previously known as *Loboa loboi*). This infection is mainly found in the tropics of South and Central America, with sporadic cases in Africa and other areas of the world. The organisms are thought to reside in soil or vegetation and infect humans via skin trauma. Farmers, hunters, and jungle workers are affected more than others. Dolphins can also be infected, so it is presumed that *L. loboi* also exists in bodies of water. The disease occurs as slowly forming skin nodules of various sizes that occur on the face, arms, legs, and feet. The lesions can differ in appearance and can be flat or nodular and warty or ulcerated. Infection can exist over a period of years, with slow progression of the disease, which is relatively asymptomatic. Special staining of lesion biopsy material is required to demonstrate the characteristic short chains of lemon-shaped fungal cells. *L. loboi* has never been isolated in culture. The only effective treatment is surgical excision, although clofazimine may be partially effective. The infection is generally resistant to therapy with the antifungal medications typically used to treat other invasive cutaneous mycoses, although posaconazole has proven successful in at least one case.

Nodular lymphangitis

Nodular lymphangitis, or lymphocutaneous syndrome, is an entity characterized by inflammatory nodules that occur along lymphatic vessels that drain an area of primary skin infection (Fig. 33.12). Certain organisms are commonly associated with nodular lymphangitis, including *Sporothrix*

schenckii, *Nocardia*, and mycobacteria, although other, more unusual infectious agents can also be involved (Box 33.2).

Sporotrichosis

Sporotrichosis is the most frequently recognized cause of nodular lymphangitis. The agents of this disease include *S. schenckii* as well as the more newly identified species *S. brasiliensis*, *S. globosa*, and *S. luriei*, each of which has unique epidemiologic and virulence characteristics. *S. brasiliensis* was initially confined to Brazil, although it has since been found in other areas of South

Mycobacterium kansasii
Mycobacterium chelonae
Mycobacterium abscessus
Mycobacterium fortuitum

Bacteria

Staphylococcus aureus
Francisella tularensis
Bacillus anthracis

Viruses

Herpes simplex virus

America. *S. globosa* is uncommon, but it has been identified throughout the world and is the main cause of sporotrichosis in China. For the purposes of this discussion, we will use the term *S. schenckii* complex to refer to all species of *Sporothrix*. *Sporothrix* complex organisms are known as *dimorphic* because of their ability to exist either as a yeast (at higher temperatures, as in human tissue) or in hyphal form (in the environment, at temperatures <37° C). Sporotrichosis is typically an occupational disease of gardeners, farmers, and horticulturalists. Introduction of the fungus through the skin occurs by pricks of thorns or barbs; handling sphagnum moss or slivers from wood or other material contaminated with the organism has also been identified as a risk for infection. However, *S. brasiliensis* and, to a lesser extent, *S. schenckii* display zoonotic transmission, with cats being the source.

Sporotrichosis is usually localized to the skin and subcutaneous tissues. However, dissemination to bone, lungs, brain, and other organs can occur in immunocompromised persons, and pulmonary disease can occur when *S. schenckii* complex conidia are inhaled. Cutaneous disease begins as an erythematous painless nodule at the inoculation site, which may ulcerate and remain confined (cutaneous form) or grow and spread proximally, with surrounding satellite nodules along the lymphatic channels (lymphocutaneous form or nodular lymphangitis). Laboratory confirmation of sporotrichosis is made by culture of pus or exudate on SDA, preferably aspirated from an unopened lesion, and growth may take up to 30 days. The characteristic oval- to cigar-shaped yeasts are rarely visualized by direct smear of pus because the organisms are often few, but Grocott-Gomori methenamine silver and other fungal stains of tissue obtained from biopsy are useful in identifying the fungus. Molecular tools such as PCR may be required to distinguish the species.

Itraconazole is the first-line treatment for cutaneous sporotrichosis. Orally administered terbinafine also has activity and is an alternative therapy. There is less experience with newer azoles, but posaconazole has good in vitro activity, unlike isavuconazole. More severe or disseminated disease is treated with amphotericin B. Heating tissues to 42° to 43°C has also been effective in decreasing the size of lesions because *S. schenckii* complex grows best at lower temperatures. Local hyperthermia may be useful for mild cutaneous disease in pregnant women to avoid the toxicity of antifungal therapy.

Nocardiosis

Nocardia spp. are ubiquitous in the environment and may be found in soil, water, and vegetation. They are part of the aerobic actinomycetes group that also includes *Corynebacterium*, *Rhodococcus*, *Gordonia*, *Tsukamurella*, *Streptomyces*, *Actinomadura*, and *Mycobacterium*. More than 40 characterized *Nocardia* spp. can cause human disease; in recent years, molecular techniques continue to identify new species causing infection in humans. Some of the most common recently described species reported include *N. veterana*, *N. abscessus*, *N. paucivorans*, and *N. cyriacigeorgica*. There is geographic variation in the frequency of different species.

Nocardia spp. can cause localized or disseminated infection, with the latter occurring more often in immunocompromised hosts. In the skin and soft tissue form of nocardiosis

that results from direct cutaneous inoculation, manifestations range from lymphocutaneous syndrome to subcutaneous abscesses, cellulitis, and mycetoma. The skin can also be involved through hematogenous dissemination from another source. Although *N. cyriacigeorgica*, *N. nova*, and *N. farcinica* cause most noncutaneous invasive disease, *N. brasiliensis* is the most common species causing cutaneous or lymphocutaneous nocardiosis, particularly in tropical countries. A variety of other species can also cause cutaneous disease.

Direct smears from nocardial skin lesions will show gram-positive, beaded, branching filaments. The organisms are acid-fast stain negative but can be seen with a modified acid-fast stain that uses a weaker acid to decolorize the primary stain carbol fuchsin. This feature, as well as its aerobic growth, can distinguish *Nocardia* from organisms such as *Actinomyces* that is both acid-fast and modified acid-fast negative and grows anaerobically. *Nocardia* spp. may take as long as 2 weeks to grow in blood culture media. The treatment of choice is trimethoprim-sulfamethoxazole, although other antimicrobials, such as imipenem, linezolid, and amikacin, also have good activity. There are important species differences in antimicrobial susceptibilities, with some species such as *Nocardia farcinica* being relatively resistant to several antimicrobials, so it is important to perform susceptibility testing of clinical isolates.

Mycobacterial infection

Nontuberculous mycobacteria

Nontuberculous mycobacteria (NTM) are distributed throughout the environment, and many species are known to cause cutaneous disease, including nodular lymphangitis. Skin and soft tissue infection is the most common extrapulmonary manifestation of disease caused by NTM, and recent data indicate an increasing incidence of NTM cutaneous infection over the past several decades. Puncture wounds, motor vehicle accidents, injections, cosmetic procedures including tattooing, and other surgeries are the typical precipitating factors for skin infection, although hematogenous spread to the skin from other sites can occur (see later).

Mycobacterium marinum, a marine organism; *M. ulcerans*; and rapidly growing mycobacteria (RGM) including *M. abscessus* complex, *M. chelonae*, and *M. fortuitum* group are the most common NTM isolated from skin lesions. *M. marinum* skin infection, also known as *swimming pool* or *fish tank granuloma*, develops in individuals with a history of cleaning fish tanks or exposure to saltwater or nonchlorinated swimming pools. The microorganism enters through an open wound or via traumatic inoculation of the skin. The lesions are initially solitary, red-purple in color, and located on the hands or arms 2 to 3 weeks after exposure. They are papular or nodular and can become wartlike or ulcerated. The infection can then progress to a lymphocutaneous syndrome characterized by the development of more proximal lesions along the path of lymphatic drainage of the initial site of infection.

The diagnosis is made by biopsy and culture of a skin lesion in association with a history suggestive of exposure. *M. marinum* grows best at 25° to 32° C. Treatment involves systemic antimycobacterial therapy for several months, until resolution of the lesions occurs. Combination antimicrobial

therapy with clarithromycin plus ethambutol or rifampin is generally used, although in more superficial skin infections, clarithromycin or doxycycline monotherapy may be successful. *M. marinum* is also susceptible to trimethoprim-sulfamethoxazole and linezolid. Applying local heat has also been used as an adjunctive therapy.

Lesions caused by RGM can appear as nodules, papules, plaques, or ulcers. *M. chelonae* is usually seen in immunocompromised patients, whereas cutaneous infections caused by *M. fortuitum* complex typically occur in otherwise healthy persons. *M. abscessus* complex infections are seen in both patient types. Exposure to acupuncture, dermal filler injections, tattooing, nail salons, and mesotherapy have been risk factors for infection. Healthcare-associated skin infections from steroid injections or contaminated antiseptics have occurred.

M. ulcerans infection usually occurs as a single pruritic ulcer with undermined edges, also known as a *Buruli ulcer*. *M. ulcerans* infection is not endemic in the United States but is associated with swamps and may cause a chronic infection with limb deformity in tropical climates. It grows very slowly in culture and can take up to 12 weeks of incubation. Early disease can be cured with surgical debridement.

Diagnosis of cutaneous NTM infections is made by acid-fast staining and culture of skin biopsy or drainage material. Molecular methods for species identification including partial gene sequencing or the use of gene probes is often necessary, and MALDI-TOF mass spectrometry may also be useful in determining species. Antituberculous antimicrobials do not have significant activity against most of these NTM, but antimicrobials such as fluoroquinolones, clarithromycin, aminoglycosides, imipenem, doxycycline, and cefoxitin may be used, depending on the species.

Mycobacterium tuberculosis

Cutaneous tuberculosis is uncommon, but inoculation of the skin with *M. tuberculosis* can lead to tuberculosis verrucosa cutis (TVC). TVC lesions develop as red or purple papules that become wartlike. They occur in areas of the body prone to trauma. Historically, manifestation of TVC by *M. tuberculosis* was seen in physicians and anatomists who infected themselves by contact with patients or cadavers (*prosector's wart*). In the tropics, TVC is seen in children who walk barefoot in soil contaminated with tuberculous sputum. Tuberculous chancre, a skin ulcer, is another localized dermatologic manifestation of *M. tuberculosis* following traumatic inoculation of the skin with the organisms. Cutaneous tuberculosis can also result from suppuration of an infected lymph node or bone/joint with extension to the skin, known as *scrofuloderma*. Treatment of cutaneous tuberculosis is with standard antituberculous antibiotics.

Actinomycosis

Actinomycosis is a chronic disease characterized by the formation of abscesses, tissue fibrosis, and draining sinuses that discharge sulfur granules (yellow-colored masses of organisms). It is caused by non-spore-forming anaerobic or microaerophilic bacterial species, especially *Actinomyces israelii*, although a variety of *Actinomyces* species have been identified as causing human infection. Once thought to be

Fig. 33.13 Actinomycosis of the jaw following dental infection. (Courtesy Dr. Gail Reid, Loyola University Medical Center, Maywood, IL.)

fungi because of their branching, *Actinomyces* spp. and the closely related *Nocardia* spp. are classified as higher prokaryotic bacteria. *Actinomyces* spp. are gram-positive, pleomorphic, and diphtheroidal or, more commonly, delicately filamentous. They are part of the normal biota of the mouth and GI and genital tracts. Although there are thoracic, abdominopelvic, and central nervous system (CNS) forms of the disease, involvement of the face and neck is the most common manifestation (Fig. 33.13) and often follows dental sepsis or manipulation, trauma, tonsillitis, otitis, or mastoiditis. Cervicofacial actinomycosis may extend to the underlying mandible or facial bones, leading to osteomyelitis. Penicillin is the preferred treatment.

Dermatologic manifestations of systemic bacterial and fungal infections

Systemic infections can produce skin lesions that may provide important diagnostic clues. This phenomenon may be seen in various bacterial, fungal, parasitic, and viral infections. In this section, some important dermatologic findings associated with systemic bacterial and fungal infections are discussed. Skin lesions associated with viral and parasitic infections are described later in this chapter.

Bacteria

Pseudomonas infection

Ecthyma gangrenosum is a characteristic skin lesion associated with *Pseudomonas* bacteremia. The lesions begin as painless, flat, erythematous areas, often on the legs, that progress rapidly to nodules and then bullae that subsequently ulcerate and form a black eschar on the surface, with surrounding erythema. Although ecthyma gangrenosum has classically been associated with *Pseudomonas* sepsis, such lesions have also been reported in sepsis caused by other gram-negative bacteria, *S. aureus* and *Candida*. Ecthyma gangrenosum is the result of bacterial invasion of dermal blood vessels leading to ischemia, hemorrhage, and necrosis. Biopsy and Gram-stained

smear of the lesions reveals bacteria in the tissue, and inflammation of blood vessels is also present.

Vibrio and Aeromonas infections

Vibrio vulnificus is a gram-negative organism that is part of the ocean microbiota and can cause severe disease with a high fatality rate, particularly in persons with underlying liver dysfunction. Persons with other chronic diseases such as diabetes mellitus, hemochromatosis, renal failure, or alcohol abuse are also at increased risk. Infection occurs through ingestion of contaminated shellfish, such as raw oysters, or through exposure of an existing wound to seawater containing the organisms. Patients with *V. vulnificus* sepsis can develop widespread skin lesions characterized by the formation of hemorrhagic bullae that evolve into ulcers with skin necrosis.

V. vulnificus grows well on MacConkey agar but can be overlooked among other gram-negative organisms because it usually is a lactose fermenter. In addition, *Vibrio* spp. can be isolated from stool specimens, but isolation and identification are not routinely performed in many clinical laboratories and must be specifically requested. Commercially available stool PCR panels such as the BioFire FilmArray Gastrointestinal Panel (BioFire Diagnostics) can identify *Vibrio* spp.

Aeromonas spp. are found in freshwater and brackish water and can cause skin lesions similar to those caused by *V. vulnificus*. However, skin infection caused by *Aeromonas* is often the result of contamination of a preexisting wound with water containing the organisms. Aeromonads cause a variety of infections in addition to cellulitis, including gastroenteritis, peritonitis, and cholangitis. These infections may be complicated by bacteremia and sepsis, and patients with underlying liver disease are at higher risk for invasive *Aeromonas* infection. *Aeromonas* skin infection is typically rapidly progressing, with formation of hemorrhagic bullae and skin necrosis. Osteomyelitis and myonecrosis with gas formation in the tissues may ensue, and debridement is required in this setting. *Aeromonas* infection is also a well-recognized complication of medicinal leech therapy used in reimplantation or flap procedures because aeromonads are symbionts within the leech gut. Prophylactic antimicrobial agents, typically fluoroquinolones, trimethoprim-sulfamethoxazole, or third-generation cephalosporins are advised for patients receiving leech therapy. *Aeromonas* spp. can be cultured on MacConkey agar and are oxidase-positive, which distinguishes these organisms from most Enterobacterales.

Borreliosis

The predominant tickborne spirochete of Lyme borreliosis (disease), *Borrelia burgdorferi*, characteristically produces a distinctive “bull’s eye” or target skin lesion called *erythema migrans* (EM) at the inoculation site 1 to 2 weeks after infection (Fig. 33.14). The lesions are at least 5 cm in size and may become hemorrhagic or necrotic in the center. EM is the most useful diagnostic marker where it occurs in 70% to 80% of persons with Lyme borreliosis. Over a period of weeks, multiple secondary EM lesions can occur in various regions of the body as the spirochetes disseminate. Other manifestations of Lyme borreliosis include arthritis, carditis, and neurologic

disease. In addition to recognizing EM, the diagnosis of Lyme borreliosis can be made by serologic testing to identify antibodies against *B. burgdorferi*. Ceftriaxone, penicillin G, amoxicillin, and tetracycline antibiotics are useful in the treatment of Lyme borreliosis.

A rash very similar to EM can occur in southern tick-associated rash illness (STARI). This is a disease of unknown cause that can occur after a tick bite from the lone star tick, *Amblyomma americanum*. The *Ixodes scapularis* tick, not the lone star tick, is responsible for most of the *B. burgdorferi* transmission in the United States, but *I. pacificus* ticks can also transmit *B. burgdorferi* in the Pacific Northwest. Lyme borreliosis is endemic in the upper Midwest, Northeastern, and mid-Atlantic United States. Lone star ticks are found in the eastern, southeastern, and south-central areas of the United States.

A nonspecific petechial, macular, or papular rash is commonly seen during the end of the primary febrile episode of relapsing fever caused by *Borrelia recurrentis*. The disease is transmitted by human body lice and affects predominantly homeless persons or those in conditions of poor hygiene. It has become uncommon in the United States and is now primarily found in northeastern Africa. Diagnosis of relapsing fever is made by demonstrating *Borrelia* organisms in the peripheral blood of febrile patients using dark-field microscopy or Giemsa- or Wright-stained thick and thin blood smears.

Treponema infection

Syphilis is a sexually transmitted infection caused by *Treponema pallidum* subsp. *pallidum* that may be acute or chronic. Characteristic clinical manifestations differ depending on the length of time that has elapsed since infection. Cases of syphilis have been on the increase in the United States, particularly among men who have sex with men, especially those with HIV infection. The primary lesion usually appears as a papule at the inoculation site 1 to 3 weeks after the initial exposure, though it can occur as late as 3 months after exposure. Erosion and ulceration then occur, forming the characteristic painless

Fig. 33.14 Erythema migrans rash of Lyme borreliosis (disease). (Courtesy Dr. Gail Reid, Loyola University Medical Center, Maywood, IL.)

syphilitic chancre (Fig. 33.15) that is indurated or rubbery, in contrast with the painful soft chancre of chancroid caused by *Haemophilus ducreyi*. Lesions often occur on the genitalia but can develop at any site of inoculation, including the mouth, rectum, or hands. Multiple chancres can occur, particularly in those with HIV infection.

Spontaneous resolution of the primary lesion(s) occurs within several weeks, and this is followed by the secondary stage of syphilis 2 to 8 weeks later. Secondary syphilis usually involves the skin and mucous membranes, although inflammation of organs such as the liver, CNS, bones, or eyes may occur. The rash of secondary syphilis is characterized as a diffuse, painless, maculopapular rash (Fig. 33.16), and involvement of the palms and soles is characteristic. Highly infectious lesions known as *mucous patches* may occur on the lips, oral mucosa, or genital mucosa. Systemic complaints, including fever, malaise, and enlarged lymph nodes, commonly accompany secondary syphilis.

Secondary manifestations also disappear spontaneously within weeks. Subsequently, the infection remains clinically latent for weeks to years and may evolve into tertiary disease affecting predominantly the CNS and heart. Diagnosis can be

Fig. 33.16 The rash of secondary syphilis.

made based on physical findings and serologic tests. *T. pallidum* cannot be detected by Gram stain but can be visualized by darkfield microscopy, a technique that is not widely available in laboratories. Sometimes, spirochetes can be seen on silver-stained biopsy materials, but silver staining of biopsy materials is rarely performed. *T. pallidum* cannot be grown on artificial media. Serologic methods are often used to diagnose infection.

Zoonoses

Zoonotic diseases are those transmitted to humans by wild or domestic animals. There are hundreds of zoonotic diseases. This section examines some of the more common systemic bacterial **zoonoses** that have significant dermatologic manifestations.

Rickettsiosis

Dermatologically, rickettsial infections are characterized by the type and distribution of the associated rash (e.g., petechial or vesicular; centripetal; or centrifugal) and the presence or absence of a black eschar at the vector bite inoculation site. Clinical symptoms common to rickettsial infections include high-grade fever, chills, malaise, headache, myalgias, rash, and conjunctival injection. Systemic and cutaneous disease manifestations are the result of widespread inflammation of small blood vessels (**vasculitis**).

Rickettsiae are gram-negative intracellular pathogens that reside within endothelial cells and macrophages. Rickettsiae have various animal reservoirs and are transmitted to humans through several species-specific insect vectors (e.g., ticks, mites, lice, fleas). There are two general groups of rickettsiae: the spotted fever group, which are predominantly transmitted by ticks with a few exceptions, and the typhus group, transmitted by insects (fleas or lice). There are more than 30 species of rickettsiae including two typhus group species, and many are human pathogens.

Rocky Mountain spotted fever (RMSF), caused by *Rickettsia rickettsii*, is the most frequently seen rickettsial infection in the United States and is transmitted by several different species of ticks in the genera *Dermacentor*, *Amblyomma*, and *Rhipicephalus*, depending on geographic location. Contrary to its name, RMSF is usually reported in the eastern United States; the highest rates occur in Arkansas, Missouri, North Carolina, Oklahoma, and Tennessee. Most cases occur in the spring and summer, when arthropods are more active.

The incubation period of RMSF is 2 to 14 days, although many patients with RMSF do not recall a tick bite. Headache, fever, and myalgias often occur first, followed by a maculopapular rash on the extremities 3 to 5 days after illness onset. The rash occurs in about 90% of patients and usually starts at the wrists and ankles, classically involves the palms and soles (though not always), and spreads rapidly and centripetally to most of the body. **Petechiae** and purpura represent extravasation of blood from blood vessels into the skin because of the cutaneous vasculitis, and skin necrosis or gangrene may occur. RMSF is fatal within 1 to 2 weeks if appropriate therapy is not administered. The clinical syndrome of RMSF may be confused with atypical measles, mononucleosis, disseminated meningococcal or gonococcal infection, other forms of bacterial sepsis,

secondary syphilis, typhoid fever, enteroviral infection, and leptospirosis.

Because culture of these organisms is difficult, diagnosis is made based on clinical presentation and serology. The low bacterial burden in the blood limits the sensitivity of PCR assays. *R. rickettsii* is resistant to many common antimicrobial agents, but the infection is generally successfully treated with doxycycline or chloramphenicol if therapy is given early in the disease course.

Boutonneuse fever, also known as *Mediterranean spotted fever*, is the most severe spotted fever rickettsiosis after RMSF and is caused by *Rickettsia conorii*. It is characterized by the *tache noir* (black spot) or eschar at the site of the tick vector bite. This illness is not endemic in the United States but can be seen in travelers returning from India, Pakistan, Africa, and eastern and southern Europe in areas around the Mediterranean Sea. The skin lesion is the result of endothelial injury in soft tissues with necrosis and perivascular edema. Rickettsialpox, caused by *Rickettsia akari*, is also one of the spotted fever group of rickettsial diseases, but it is transmitted by the bite of mites, rather than ticks, and mice are the reservoir. The organism occurs worldwide but was initially found in New York City. Clinical findings include fever, rash, and eschar. The eschar develops from a papule that vesiculates. The rash spares the palms and soles, is papular and vesicular, and leaves black crusts. These illnesses are treated similarly to RMSF, with doxycycline or chloramphenicol.

Typhus fever is caused by two species of rickettsiae, *R. prowazekii* and *R. typhi*. The former causes epidemic or sylvatic typhus and is transmitted by human body lice, and the latter causes murine typhus and is transmitted by fleas. Epidemics occur in conditions of poor hygiene. Symptoms include fever, headache, myalgias, and a macular erythematous rash. Diagnosis is made serologically, and treatment is with doxycycline.

Scrub typhus, caused by *Orientia tsutsugamushi*, is transmitted via the bite of a chigger (mite larval stage). It is distributed worldwide in rural areas with high grass and brush, particularly in India, China, Southeast Asia, and Russia. An erythematous papule occurs at the site of the bite followed by ulceration and eschar formation. A macular faint rash involving the trunk and extremities often occurs. Systemic symptoms include fever, headache, myalgias, and lymphadenopathy. Serologic testing is typically used for diagnosis, and treatment is with doxycycline.

Leptospirosis

Leptospirosis is a zoonotic disease usually caused by *Leptospira interrogans*, although other *Leptospira* species can cause disease. *Leptospira* species are spiral aerobic spirochetes distinguished from other spirochetes by their hooked ends. The organisms are carried in the renal systems of rodents and other mammals, including dogs and livestock. Humans become infected after direct contact with an infected animal or indirect contact with the urine or tissues of infected animals in vegetation, soil, or water. Leptospirae can remain viable in the environment for months.

The infection is found throughout the world, particularly in tropical and subtropical areas, and the highest incidence in the United States is in Hawaii. Leptospirosis commonly

involves the kidneys, liver, and CNS. It can be a self-limited illness, or it can be fatal with renal and liver failure and pneumonia. The rash of leptospirosis is maculopapular and may become hemorrhagic. Like *Treponema*, *Leptospira* can be seen by darkfield microscopy, but the technique is neither sensitive nor specific and not widely available, and the diagnosis of leptospirosis is usually made serologically. The organisms can be cultured, but culture is a slow and insensitive technique. Penicillin G, ceftriaxone, and doxycycline are generally effective for treatment.

Bartonellosis

The most common forms of human bartonellosis are caused by *Bartonella henselae* and *Bartonella quintana*. *Bartonella* spp. are gram-negative intracellular bacteria transmitted by insects such as phlebotomine sandflies, human body lice, and cat fleas or by animal scratches or bites. They can cause acute and chronic infections and blood vessel proliferation. *B. henselae* is the cause of cat scratch disease (CSD), which is transmitted by cat scratches or bites. Cat fleas may also be a vector for *B. henselae*. The initial lesion of CSD is a papule, pustule, or vesicle, usually on the arm, followed by the development of regional lymphadenopathy associated with fatigue, fever, and malaise. The infection can resolve spontaneously after weeks to months, and antimicrobials generally fail to affect the course. *B. quintana* is transmitted by louse vectors and associated with poor sanitation and hygiene.

Both *Bartonella* spp. can cause bacteremia and endocarditis as well as the main dermatologic disease of bartonellosis, bacillary angiomatosis (BA), which is predominantly seen in HIV-infected persons, although infections have also been described in solid organ transplant recipients. BA is caused by new blood vessel formation in the skin or other organs, such as the liver (known as *peliosis hepatis*). The skin lesions that occur in crops are generally nodular and red or purple and can ulcerate. The size of the lesions ranges from several millimeters to centimeters, and they bleed easily with trauma. They are most prominent on the extensor surfaces of the limbs. The organism may be cultured from skin and subcutaneous lesions or occasionally from blood, but *Bartonella* spp. are fastidious and may require more than 1 week of incubation on specialized media. Diagnosis can also be made by serologic testing, PCR of blood, or histopathologic demonstration of organisms in tissue specimens using Warthin-Starry staining.

Rat bite fever

Two bacterial diseases, which are rare in the United States, are included under the general term *rat bite fever*: streptobacillosis, caused by *Streptobacillus moniliformis*, and spirillosis, caused by *Spirillum minus*. The majority of U.S. and European cases are caused by *Streptobacillus*, whereas *S. minus* infections occur predominantly in Asia. These gram-negative organisms are part of rodent oral biota. Rat bite fever is usually transmitted by bites or scratches from rodents or carnivores that ingest rodents, but streptobacillosis has also occurred after ingestion of food contaminated by rodent excrement. The diseases share clinical and epidemiologic characteristics. An abrupt onset of fever and chills, headache, and muscle pain is followed shortly by a maculopapular or sometimes petechial,

vesicular, or pustular rash that is most marked in the extremities, may become purpuric, and can lead to desquamation. The rash involves the palms and soles, and the illness can mimic RMSF or secondary syphilis. In *S. moniliformis* infection but not *S. minus* infection, joint swelling and pain often occur in association with the rash.

Laboratory confirmation is made by isolation of the causative organism after inoculating material from the primary lesion, lymph node, blood, joint fluid, or pus into culture media or laboratory animals. *Streptobacillus* characteristically forms filaments and beadlike chains on Giemsa or Gram-stained smears, and *S. minus* appears as thick, coiled spiral rods. Serum antibodies may be detected in *S. moniliformis* but not *S. minus* infection, and PCR and MALDI-TOF mass spectrometry have been used for diagnosis of *S. moniliformis* infection. Penicillin G is the treatment of choice for both infections.

Tularemia

Tularemia, also known as *rabbit fever*, is caused by *Francisella tularensis*, a gram-negative coccobacillus. The disease occurs in six forms, including glandular, ulceroglandular, oculoglandular, pneumonic, oropharyngeal, and septicemic or typhoidal. The type and severity of disease depend on the subspecies or strain of infecting bacteria, dose, and route of infection. Transmission can occur through contact with infected animals (especially rabbits and small rodents), contact with contaminated water or soil, or from arthropod bites. The most common form of the disease is ulceroglandular, in which the infection is inoculated directly into the skin after handling infected rabbits, rodents, and other wild animals or, less commonly, domestic animals such as sheep or cats. This form of infection can also develop after the bite of infected fleas, ticks, deerflies, and mosquitoes. It presents as an indolent painless ulcer, often on the hand, accompanied by painful swelling of the regional lymph nodes. Some patients can have nodular lymphangitis. Infection that manifests as lymphadenopathy without report of an ulcer is termed *glandular*. The other forms of tularemia can occur via inoculation of the conjunctiva (oculoglandular) or inhalation of bacteria from the environment (pneumonic). Pulmonary infection may also occur from hematogenous spread from another site of inoculation. All forms may be associated with maculopapular or vesicular rash and erythema nodosum, urticaria, and erythema multiforme.

Diagnosis of tularemia is usually made by demonstrating specific antibodies in the patient's serum, as early as 1 week after onset of symptoms. Standard antibody detection is by indirect immunofluorescence assay or microagglutination methods. Examination of ulcer exudates, lymph node aspirates, and other specimens using a fluorescent antibody test may provide a rapid diagnosis, although the organism is not often seen on Gram stain. PCR methods have been developed to detect *Francisella* DNA in clinical specimens, and MALDI-TOF mass spectrometry analysis can rapidly identify the organism from culture. *Francisella* is fastidious but will grow on chocolate, modified Thayer-Martin, and buffered charcoal-yeast extract agars using material from lesions, blood, or sputum. Laboratory isolation of *Francisella* constitutes a critical value. Great care must be exercised with culturing the organism because of its highly infectious nature. Infection by *Francisella* is a potential occupational hazard for laboratory workers. Streptomycin with or

without tetracycline has been the traditional treatment, but because of the potential for ototoxicity and nephrotoxicity, streptomycin is generally reserved for more serious cases. Doxycycline and fluoroquinolones are effective treatments for uncomplicated cases.

Mycobacteria

Nontuberculous mycobacteria and tuberculosis

As noted earlier in this chapter, NTM can cause localized cutaneous infection, generally as the result of skin inoculation via trauma, sometimes extending to bone and joints (Fig. 33.17). These infections can also become disseminated. This typically occurs in the setting of impaired immune function, as in persons with HIV, organ transplantation, and cancer. Patients with central venous catheters may develop NTM catheter-related infections that can spread hematogenously to various organs, including the skin. These infections are usually the result of rapidly growing mycobacteria including *M. fortuitum*, *M. chelonae*, *M. abscessus* complex, and *M. mucogenicum*. The characteristics of the skin lesions and their treatments are like those noted earlier for localized cutaneous disease caused by NTM.

M. tuberculosis can spread to the skin through the lymphatic system and bloodstream to distant sites and cause a variety of skin manifestations. Hematogenous spread to cutaneous sites leads to nodular swellings of the skin forming tuberculous gummas (skin abscesses) or lupus vulgaris, the most common form of cutaneous tuberculosis. Lupus vulgaris is characterized by sharply circumscribed, red-brown plaques or ulcers of the head and neck. The infection can be progressive and can destroy cartilage of the nose or ears. Lesions may be nodular, scaly, or ulcerated. Skin biopsy and mycobacterial culture often make the diagnosis, although organisms may not be seen in biopsies of lupus vulgaris as they tend to be few. Other forms of cutaneous tuberculosis are the result of hypersensitivity reaction rather than significant skin infection with

Fig. 33.17 Subcutaneous nodules and cellulitis caused by disseminated *Mycobacterium chelonae*.

the organism. For example, erythema induratum of Bazin can develop in patients with extracutaneous tuberculosis, characterized by multiple tender, indurated nodules, typically on the legs. Biopsy of these lesions shows inflammatory changes, including vasculitis and panniculitis, but organisms may not be detected. However, the lesions do respond to antituberculous therapy.

Leprosy

Leprosy, also known as *Hansen disease*, is found in South Asia, Africa, and South America. Cases reported from the United States are typically in immigrants from these endemic areas. In addition, genetic factors appear to influence susceptibility to Hansen disease and the disease manifestations. The classic skin manifestation of *Mycobacterium leprae*, the causative agent of Hansen disease, is a circumscribed, hypopigmented, or less commonly, reddish, hyperpigmented macule (Fig. 33.18). However, lesions can also be papular or nodular, and affected skin may have decreased or no hairs.

Two polar types of Hansen disease occur, tuberculoid or lepromatous, with three recognized gradations occurring between these two extremes. Classification is based on the number and appearance of the skin lesions, nerve involvement, and systemic or mucosal involvement. Tuberculoid leprosy, the mildest form, is characterized by few skin lesions with a paucity of mycobacteria in the lesions and a strong host cell-mediated immune response with extensive lymphocyte infiltration and granulomas. Patients with lepromatous leprosy, the most severe form, have several lesions with many mycobacteria, infiltration of the peripheral nerves, and a poor cell-mediated response with fewer lymphocytes and granulomas. Because the peripheral nerves are infiltrated with organisms and may be injured by the host immune response, there is nerve dysfunction, and the skin lesions are often anesthetic. *M. leprae* has a predilection for the cooler parts of the body, such as the ears and nose. The main mode of spread is via infected respiratory or nasal secretions, although leprosy is not easily transmitted. Acid-fast bacilli and granulomas can be seen in tissue biopsy specimens, but *M. leprae* has not been cultured in vitro, except in live animals. Effective treatment usually involves combination chemotherapy with agents such as rifampin, dapsone, and clofazimine.

Fungi

Candidiasis

Skin lesions can be a clue to the diagnosis of invasive forms of *Candida* infection, such as candidemia. An erythematous maculopapular, pustular, or nodular rash may be associated with systemic *Candida* infection. The lesions represent subcutaneous *Candida* abscesses. Skin biopsy will reveal fungal pseudohyphae with inflammatory cells, and *Candida* can be grown from culture of the aspirate or biopsy.

Systemic dimorphic fungi and molds

S. schenckii (see earlier), *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis* are the most common systemic dimorphic fungi. These fungi often cause disease in healthy hosts, unlike opportunistic fungi, such as *Aspergillus*. They are known as *dimorphic fungi* because they exhibit different morphologies at different temperatures, existing as molds in the environment at 22° to 30° C but as yeasts at body temperature. Within the United States, *Histoplasma*, *Blastomyces*, and *Coccidioides* are distributed in specific geographic areas: *Histoplasma* in the Ohio and Mississippi River Valleys; *Blastomyces* in the Midwest, South Central, and Southeastern United States; and *Coccidioides* in the Southwest.

These three genera usually enter the body via the respiratory tract and primarily cause pneumonia, but all can become systemic and produce secondary skin or mucosal lesions through hematogenous spread. The skin is the most common extrapulmonary site of *Blastomyces* infection. Well-circumscribed tender nodules (Fig. 33.19), ulcers, or plaques can occur anywhere on the body, often on the exposed areas of the head, neck, or extremities. The lesions are typically verrucous and can ulcerate or form abscesses that drain purulent fluid. The skin manifestations of blastomycosis may be mistaken for pyoderma gangrenosum, NTM infections, skin cancer, or other fungal infections.

Skin biopsy reveals neutrophilic and granulomatous inflammation with broad-based budding yeasts with a

Fig. 33.19 Nodular skin lesion caused by *Blastomyces dermatitidis*. (Courtesy Dr. Gail Reid, Loyola University Medical Center, Maywood, IL.)

doubly refractile cell wall, 8 to 15 µm in size. Silver and periodic acid–Schiff stains are helpful in identifying the organisms that will also grow on SDA. In addition, urine and serum antigen assays are available to detect *Blastomyces*. These tests are often positive in disseminated disease. The organisms are sometimes isolated from blood cultures.

Compared with *Blastomyces*, *Histoplasma* is less often associated with skin lesions, but when cutaneous manifestations of histoplasmosis do occur, they can be papular, nodular, plaquelike, or ulcerated, or they may take the form of cellulitis. Disseminated histoplasmosis is an opportunistic infection in persons with AIDS, organ transplant recipients, or those receiving immunosuppressive medications such as tumor necrosis factor α (TNF- α) antagonists (e.g., infliximab) for the treatment of inflammatory diseases such as rheumatoid arthritis or Crohn disease. Cutaneous lesions are not uncommon in this setting and may be accompanied by oral and GI tract ulcers or nodules caused by *Histoplasma*. Sometimes, oral lesions are the only manifestation of histoplasmosis.

The diagnosis is made similarly to that of blastomycosis, using skin biopsy and culture. *Histoplasma* yeasts are smaller than *Blastomyces*, 2 to 4 µm in size, and are thick walled with narrower-based budding. As with blastomycosis, *Histoplasma* urine and serum antigen tests are available to assist in diagnosis, and blood cultures may be positive in disseminated disease.

One of the most common areas of the body to which *Coccidioides* spreads is the skin, which may be the only clinical manifestation of disease. Lesions can be maculopapular, verrucous, ulcerated, or fluctuant abscesses, with a propensity to involve the scalp and face. Diagnostic methods for coccidioidomycosis are like those for histoplasmosis and blastomycosis, namely, tissue biopsy, culture, and antigen testing. *Coccidioides* is highly contagious, so the laboratory should be notified that it might be present when clinical material is sent for culture. In tissue, *Coccidioides* organisms appear as 10- to 80-µm thick-walled spherules that may contain endospores and neutrophilic infiltrates surrounding the spherules. In addition, serum antibody testing for coccidioidomycosis is useful for diagnosis. For all the endemic fungi, systemic antifungal therapy with amphotericin B (for severe disease) or azoles is generally effective.

Disseminated mold infections, including those caused by *Aspergillus*, those that cause mucormycosis (see earlier), and those caused by *Fusarium* are serious infections with high mortality rates. Patients become infected by these fungi via inhalation of fungal spores, ingestion of contaminated food, or skin trauma. They invade blood vessels and often spread, including to the skin. Cutaneous lesions are typically black and necrotic, with eschar formation. These infections generally have a poor prognosis as they tend to occur in severely immunocompromised persons such as bone marrow transplant recipients or persons with acute leukemia.

A diagnosis is made by observing characteristic fungal hyphae on tissue stain and fungal culture of a suspicious skin lesion. In addition, *Fusarium*, unlike other molds, can be recovered in blood cultures. In an immunocompromised patient, the presence of one of these molds, particularly *Fusarium* or one of the agents of mucormycosis, in a culture or tissue stain is a critical value and should be communicated to the patient's health care provider immediately. Amphotericin B or mold-active azoles are used for these infections.

Viral infections

Viruses are intracellular parasites that require a living, nucleated cell to replicate. Viruses can produce localized or disseminated disease and, in some cases, cause chronic infection by evading the host immune system (e.g., HIV, hepatitis C virus). They can cause direct damage to tissues or evoke an immune response that leads to disease manifestations. The viruses commonly associated with skin and soft tissue infections are discussed in this section.

Rubeola

Rubeola, also known as *measles*, is caused by a paramyxovirus (family Paramyxoviridae, genus *Morbillivirus*) and is spread by direct contact with respiratory secretions of infected persons. Measles is one of the most communicable of all infectious diseases, but after vaccination became available in the 1960s, the number of cases in the United States decreased sharply, and the illness was considered controlled in the United States in 2000. However, there has been a recent marked increase in measles cases. In 2019, more than 700 cases occurred in the United States, the largest number in the 21st century. About 70% of those cases were in unvaccinated patients, and almost all were residents of the United States.

After an incubation period of 10 to 14 days, the clinical features of coryza, conjunctivitis, and cough develop, followed by the appearance of Koplik spots. These are small red patches with central bluish-gray specks on the buccal mucosa near the second molars. Shortly thereafter, a maculopapular rash occurs. The rash spreads from the face downward to the trunk and extremities and affects the palms and soles. Patients with measles are most infectious during the late prodromal phase of the illness, when cough and coryza are at their peak. However, the disease is contagious from several days before the rash to several days after its onset. Measles can cause pneumonia or be complicated by secondary bacterial pneumonia, and it may cause meningoencephalitis, particularly in immunocompromised persons.

Viral isolation is difficult because of slow growth of the virus and the limited number of cell types in which it can grow. The diagnosis is usually based on signs and symptoms, but PCR for viral RNA can be performed from a throat, nasal, or posterior nasopharyngeal swab. Confirmation can also be performed via serologic testing for antibody titers.

Rubella

Rubella, also known as *German measles*, is a viral infection of children and adults that resembles measles. It is characterized by fever, rash, and lymphadenopathy. The virus is in the family Togaviridae and the genus *Rubivirus*. Rubella virus is spread in droplets shed from the respiratory secretions of infected persons. The contagious period extends from about 10 days before appearance of the rash to 15 days after onset, but it is maximal 7 days before to 7 days after onset. Many rubella infections are subclinical. For symptomatic persons, a nonspecific maculopapular rash begins on the face and moves down the body, often accompanied by cervical and

occipital lymphadenopathy and, at times, splenomegaly. The disease is clinically milder than measles, although arthritis, myocarditis, and encephalitis can be complications, and serious congenital defects (e.g., cataracts, heart defects, and deafness) can be a consequence when the infection occurs during pregnancy.

Like measles, culture of rubella virus is cumbersome and often not available; therefore diagnosis can be made by PCR detection of the virus from urine, throat, or nasopharyngeal specimens. Diagnosis can also be made by serum antibody testing if there is an increase in antibody titers over several weeks. Congenital rubella infection is often diagnosed by identifying rubella virus nucleic acids by PCR in infant specimens.

Parvovirus B19 infection

Erythema infectiosum, or fifth disease, is one of the common viral **exanthems** of childhood. Most persons encounter this infection at some point—up to 80% of adults are seropositive, depending on the population surveyed. It is caused by human parvovirus B19 (family Parvoviridae, genus *Erythroparvovirus*), which replicates in erythrocyte precursor cells. The primary mode of transmission is thought to be via the respiratory route, although vertical transmission to the fetus can occur during pregnancy, and transmission has occurred through blood product transfusion.

Fifth disease is characterized by a bright red rash of the face (so-called *slapped cheek* appearance) followed in 1 to 4 days by a fine, lacelike rash on the trunk or extremities. The rash may fade quickly, only to recur during the ensuing 2 to 3 weeks on exposure to sunlight or heat. Infection is generally not associated with fever, although mild constitutional symptoms may precede the rash. **Scarlet fever** and rubella are other childhood diseases to be distinguished from fifth disease. Variation of the rash can include the “glove-and-socks” distribution of the skin lesions, which, in this case, tend to be papular, petechial, pustular, or bullous. Complications of parvovirus B19 infection are more common in adults, and some patients can develop a symmetric arthralgia and arthritis. In those with hemolytic disorders and immunosuppressed persons (e.g., those with HIV or organ transplantation), parvovirus B19 can cause marked inhibition of red blood cell formation with extremely low red blood cell counts. Parvovirus B19 infection in pregnancy can lead to hydrops fetalis and miscarriage. Diagnosis is often made by detecting the virus in blood or bone marrow with PCR assay. Serious manifestations of infection are treated with intravenous immunoglobulin (IVIG) and blood transfusion; no antiviral medication is available.

Enteroviral infections

Coxsackieviruses and echoviruses, members of the family Picornaviridae and genus *Enterovirus*, cause a variety of exanthems. Enteroviral infections are more prevalent in the summer and fall months in temperate climates and occur year-round in tropical regions. Most infections occur in children, particularly infants, and mucocutaneous features are also found more commonly in infants and children than in adults. Enteroviruses are predominantly spread via the fecal-oral

route but at times may be spread by respiratory secretions. Most enteroviral infections are asymptomatic or result in a brief febrile illness or upper respiratory tract infection, but coxsackie viruses and echoviruses can cause more serious disease, including aseptic meningitis or encephalitis, acute flaccid paralysis, hemorrhagic conjunctivitis, pericarditis, myocarditis, and pleuritis. Enteroviruses are also the cause of many different exanthems, some of which have oral mucosal involvement. These are generally benign diseases and can resemble other viral causes of rash. They are grouped as rubelliform or morbilliform (resembling rubella or measles), roseoliform (resembling roseola), or herpetiform (resembling herpes) exanthems.

Enteroviruses can also produce petechial or purpuric-type rashes resembling those of meningococcal septicemia. A common rash associated with a number of different enterovirus serotypes is herpetiform hand, foot, and mouth disease (HFMD). HFMD primarily occurs in young children and is characterized by fever, throat pain, and vesicles on the palate, tonsils, and tongue that evolve into painful ulcers. Erythematous papules and vesicles that resemble HSV or varicella-zoster virus (VSV) lesions can also occur on the lateral and plantar aspects of the feet, palms, dorsal fingers, and sometimes the buttocks and genitalia. Herpangina is another form of mucosal disease that can occur, predominantly caused by coxsackieviruses, and is characterized by fever, throat pain, and vesicular lesions on the soft palate and posterior oropharynx. It may be confused with other causes of pharyngitis.

Viral culture of stool, throat, or involved tissue can be performed to make a diagnosis but is rarely performed. Serologic testing demonstrating a fourfold increase in antibody titer can also be used. Most commonly, PCR testing of the oropharynx, stool, or vesicle fluid establishes the diagnosis.

Herpesviridae

There are hundreds of Herpesviridae viruses, although only eight are common causes of human infection. All eight can lead to dermatologic disease, but some, such as VZV and HSV, are associated with more prominent skin findings.

Varicella-zoster viral infections

Varicella infection, or chickenpox, is a common childhood illness acquired by respiratory inhalation of VZV. The skin lesions of primary VZV infection become apparent approximately 2 weeks after initial exposure. The lesions begin as vesicles or small blisters on an erythematous base (“dew drop on a rose petal”). The lesions become pustular or rupture and form eschar over a period of several days. The rash starts on the trunk and face and then spreads to the extremities. A characteristic of chickenpox is the presence of lesions in various stages of development. When primary VZV infection occurs in adults, it tends to be more severe and systemic, involving the lungs, CNS, and liver.

Treatment with the antiviral agent acyclovir is recommended for immunosuppressed individuals and patients with visceral involvement. Routine administration of varicella vaccine to children in the United States has been 98% effective (after two doses) in preventing disease caused by VZV with little waning of immunity over time. The use of

the vaccine has resulted in a decrease in hospitalizations and deaths caused by VZV infection.

VZV, like other members of the family Herpesviridae, produces lifelong latency in the human host. After primary infection, the virus enters peripheral nerves and persists within the dorsal root ganglia. The virus may be reactivated under various conditions, most importantly by immunosuppression associated with age, certain diseases, or drug therapies (e.g., corticosteroids, cytotoxic chemotherapy). With reactivation, the virions move along peripheral sensory nerves of the skin and produce a vesicular eruption in a unilateral dermatomal distribution (Fig. 33.20). The resulting condition is called *herpes zoster* or *shingles*. The vesicles are like those of chickenpox but remain localized along sensory nerves. The disease is generally benign but may lead to postherpetic neuralgia, a syndrome of lingering pain at the site of the healed rash. In addition, when the face is involved, the virus may spread along the ophthalmic branch of the trigeminal nerve to the eye (zoster ophthalmicus), resulting in sight-threatening disease. In immunosuppressed patients, the virus may spread widely to the skin and to internal viscera such as the lungs, meninges, brain, and liver. The Centers for Disease Control and Prevention recommends two doses of the recombinant vaccine Shingrix (GlaxoSmithKline, Brentford, United Kingdom) in persons over 50 years of age to prevent shingles.

The diagnosis of chickenpox or herpes zoster is often made clinically given the characteristic epidemiologic and presenting features but can be confirmed by taking a scraping of the base of a vesicular lesion and performing PCR. Viral culture was once the standard for diagnosis but is slow, labor-intensive, and less sensitive than PCR. Culture may be required in the unusual setting of suspected antiviral resistance and the need for testing antiviral drug susceptibility. Direct fluorescent antibody (DFA) testing is also available to obtain a rapid diagnosis from a tissue scraping. Acyclovir or the orally administered prodrugs valacyclovir and famciclovir are used for the treatment of herpes zoster. Intravenously administered acyclovir is given for severe or disseminated disease.

Herpes simplex viral infection

HSV types 1 and 2 cause some of the most common skin and mucous membrane infections affecting humans. HSV infections occur after contact of mucous membranes or abraded skin with infected secretions. Initial infection may lead to the characteristic vesicular skin lesions at the site of infection or may be asymptomatic. After penetrating the skin or mucosa, the virus enters nearby neurons and leads to a lifelong latent infection in neuronal ganglia that can reactivate under various conditions, particularly immunosuppression, and cause recurrent disease. Both HSV-1 and HSV-2 can cause oral or genital infection, but HSV-1 more commonly causes orofacial infection, and HSV-2 tends to cause genital infection. An increasing proportion of genital herpes caused by HSV-1 has been noted in industrialized countries. Clinical findings cannot distinguish HSV-1 from HSV-2. Cutaneous HSV lesions are also indistinguishable from those caused by VZV, although HSV skin lesions usually do not follow a dermatomal pattern. In severely immunosuppressed hosts, such as persons with AIDS, hematologic and lymphoreticular malignancies, or organ transplants, a disseminated and life-threatening form of HSV can occur, with diffuse cutaneous lesions and lung, liver, or other visceral organ involvement.

Primary HSV-1 infection may present as severe ulcerative gingivostomatitis and pharyngitis and typically occurs in children younger than 5 years of age. This initial bout of infection is often accompanied by fever and systemic toxicity. Oral vesicles involving the soft palate, buccal mucosa, tongue, lips, and roof and floor of the mouth quickly ulcerate and may coalesce. Primary herpetic gingivostomatitis can resemble bacterial pharyngitis, herpangina caused by coxsackievirus, aphthous stomatitis, erythema multiforme major (Stevens-Johnson syndrome), infectious mononucleosis, and chemotherapy-induced mucositis. Herpes labialis, a condition commonly known as *fever blisters* or *cold sores*, is the most common manifestation of HSV reactivation. Lesions begin as superficial clear vesicles on an erythematous base on the lips or in the oropharynx. The lesions heal spontaneously and may recur in the same area. Recurrent herpes labialis is generally unaccompanied by systemic complaints, in contrast with primary infection.

Other notable cutaneous manifestations of HSV infection include eczema herpeticum, a vesicular eruption that involves areas of chronic eczema or burns and can be quite severe (Fig. 33.21), and erythema multiforme, an acute hypersensitivity reaction that manifests as target-type erythematous skin lesions that may involve mucous membranes. HSV DNA has been identified in biopsies of erythema multiforme skin lesions, and it is thought that HSV is the cause of most cases of recurrent erythema multiforme. Another presentation of cutaneous HSV is herpetic whitlow, or primary herpetic lesions of the finger (Fig. 33.22). This can be caused by HSV-1 or HSV-2. Usually a single digit is involved, with the appearance of one or more deep vesicles that may coalesce. Fever and intense local pain are often present. The condition may be misdiagnosed as bacterial paronychia, and an unnecessary incision may be performed. Recurrent herpetic whitlow can be a difficult occupational problem in medical, paramedical, and dental personnel. Herpetic whitlow in newborns (following finger sucking) and serious disseminated infection are two important neonatal herpes syndromes. Infants are infected during passage through the infected maternal genital tract.

Herpes gladiatorum outbreaks can be seen among wrestlers and are characterized by herpetic lesions of the face, hands, and chest; transmission occurs via skin trauma during wrestling matches.

HSV-2 in adults is transmitted primarily by sexual contact and results in primary and recurrent herpes genitalis and perirectal infections. Initial infection may be accompanied by fever, myalgias, and inguinal lymphadenopathy. Vesicles and ulcerations occur in the genital and/or perirectal regions. Urethritis and meningitis are potential complications. HSV-1 can also cause genital infection via orogenital contact but typically causes fewer recurrences compared with HSV-2.

The diagnosis of HSV infection can be made clinically but should be confirmed through laboratory methods, ideally via PCR of lesion scrapings. Viral culture of a vesicular or ulcerated skin lesion or biopsy of affected tissue may also be performed but is less sensitive for virus detection from ulcers compared with vesicles and for recurrent lesions compared with primary lesions. Both PCR and culture can distinguish HSV-1 from HSV-2. DFA techniques are also available to

rapidly detect HSV antigens in specimen scrapings. Type-specific serologic testing can be performed to ascertain whether a patient has been infected with HSV-1, HSV-2, or both. Acyclovir, valacyclovir, or famciclovir are the drugs of choice for HSV infections requiring treatment. Intravenously administered acyclovir is given for severe manifestations of disease.

Other herpesviruses

Mononucleosis syndromes caused by Epstein-Barr virus (EBV) and cytomegalovirus (CMV) can sometimes be associated with nonspecific rashes, which are usually maculopapular. EBV can also cause petechial or urticarial rashes and may be a trigger for erythema multiforme. The administration of penicillin therapy during mononucleosis often precipitates an immunologic reaction that leads to a pruritic, erythematous, maculopapular rash.

Human herpesvirus 6 (HHV-6) is the major cause of roseola infantum (also known as *exanthem subitum* or *sixth disease*), a febrile syndrome that occurs in infants and children. High-grade fever is present over a period of several days followed by a maculopapular rash that begins on the trunk and spreads outward. The symptoms are usually benign, although febrile seizures may be present. The diagnosis is usually made clinically, but serologic testing can be performed to confirm the diagnosis. The related human herpesvirus 7 (HHV-7) likely causes a minority of exanthem subitum cases. In immunocompetent persons, treatment for mononucleosis syndromes and HHV-6 and HHV-7 infections is supportive.

Kaposi sarcoma herpesvirus (KSHV), or human herpesvirus 8 (HHV-8), is linked to HIV-associated Kaposi sarcoma (KS) and has been found to have a role in the development of other less common malignancies. KSHV is spread mainly through sexual contact among men who have sex with men, although nonsexual transmission also occurs, possibly via saliva. KS is a vascular neoplasm; its cutaneous form is characterized by the appearance of erythematous or purplish nodules and indurated plaques that may be disfiguring (Fig. 33.23). KS may spread to the lungs, GI tract, or other organs. AIDS-related KS may regress in response to reconstitution of the immune system with antiretroviral HIV therapy, but local or systemic chemotherapy is sometimes required for treatment.

Fig. 33.21 Eczema herpeticum caused by herpes simplex virus.

Fig. 33.22 Herpetic whitlow. (Courtesy Dr. Gail Reid, Loyola University Medical Center, Maywood, IL.)

Molluscum contagiosum

Molluscum contagiosum is a common skin disease caused by a poxvirus (*Molluscum contagiosum virus*, the only member of the genus *Molluscipoxvirus*). Small, firm, waxy papules are present, often with umbilicated centers. Lesions are generally 3 to 5 mm in diameter, but occasionally giant lesions may be seen (Fig. 33.24). The virus replicates in the lower layers of the epidermis and extends upward. Molluscum contagiosum is transmitted directly from person to person, in many cases by sexual contact. It can also be spread from one area of the body to another by contact. The disease usually appears on the genitalia, face, or perirectal area. It tends to be a self-limited disease over a period of months and remains benign, although lesions can be removed for cosmetic reasons by curettage, topical chemical agents, laser, or liquid nitrogen cryotherapy.

Fig. 33.24 Giant molluscum contagiosum.

Orf and Milker nodule

Parapoxviruses (family Poxviridae), common pathogens of animals, can cause a pustular dermatitis in humans. Two of the viruses that infect humans are **orf virus** from sheep and goats and **milker's nodule virus** from cattle, also known as *pseudocowpox* or *paravaccinia virus*. These viruses are zoonotic occupational diseases of farmers, veterinarians, slaughterhouse workers, and others exposed to infected animals. The skin lesions are identical, usually a solitary papule, pustule, or nodule that can drain and develops central crusting. Lesions can be associated with local lymphadenitis. The lesions are often located on the hands, arms, or face and can be confused with anthrax. Person-to-person spread is rare, and there is no proven treatment, although topical antiviral agents such as

cidodovir and imiquimod have been used. The illness usually resolves in several weeks without scarring.

Human papillomavirus

Papillomaviruses (family Papillomaviridae) cause a variety of skin and mucous membrane lesions that range in severity from benign growths to malignancies. There are over 200 types of human papillomaviruses (HPVs), with more than 40 types that infect the oropharyngeal or genital regions. Most sexually active persons will experience HPV infection at some point in their lifetime, although infection is often transient. Most human infections are asymptomatic or lead to warts or to benign skin or mucosal cell proliferations. Common warts (circumscribed, hyperkeratotic, rough-textured, painless papules ranging in size from several millimeters to large masses), plantar warts (flat hyperkeratotic lesions of the plantar surface of the feet that may be painful), and flat warts (smooth, slightly elevated, usually multiple lesions ranging in size from 1 mm to 1 cm) are typical cutaneous manifestations. They often resolve spontaneously over time. Certain HPV strains preferentially affect the oral cavity and have been linked to oral cancers.

Genital lesions associated with HPV include venereal warts, or *condyloma acuminata*—cauliflower-like fleshy growths usually seen in the moist genital and perianal regions—and flat papillomas of the cervix. Transmission of HPV from mother to infant via infection of the birth canal can lead to laryngeal papillomas on the vocal cords and epiglottis of children. Some forms of cancer (e.g., penile, vaginal, cervical, oral, and anorectal cancers) may be associated with oncogenic types of papillomaviruses (usually HPV types 16 and 18). HPV DNA testing of cervical cells is often performed along with Pap smear testing in women and can improve the detection of early stages of cervical neoplasia. There is currently no formal indication for testing oropharyngeal, penile, or anal specimens for HPV to screen for cancer at these sites. Treatment of warts is generally with topical chemical therapy, cryotherapy, or laser therapy.

Three vaccines are currently licensed to prevent HPV infection and genital cancers, and they vary by the HPV types they target. Since 2016, only Gardasil 9 (Merck, Kenilworth, NJ) is available in the United States. It is indicated for boys and girls starting at 9 years of age and for women and men through 45 years of age to prevent genital, anal, and head and neck cancers caused by specific high-risk HPV types. In women, the vaccine is also indicated to prevent genital warts caused by HPV types 6 and 11.

Alphaviruses

Several alphaviruses in the family Togaviridae (e.g., Chikungunya, O'nyong-nyong, and Ross River viruses) are mosquito-borne and cause clinically indistinguishable syndromes of fever, arthralgia, and rash. The rash typically starts on the face and neck. As it spreads to other areas, it becomes macular or maculopapular and may be pruritic. Accompanying symptoms include headache, severe arthralgias, retro-orbital pain, pharyngitis, and vomiting. Chikungunya fever, the prototypic disease, is found in Africa, India, Southeast Asia, and areas in Europe, and has recently spread to the Caribbean and the Americas. Local transmission has been reported in the United States since 2014. Serologic

testing or blood PCR makes the diagnosis, and there is no licensed therapy.

Hemorrhagic fever viruses

Several viruses of the families Flaviviridae (e.g., yellow fever virus, dengue virus, Zika virus), Arenaviridae (e.g., Junín virus, Lassa virus, and Machupo virus), Hantaviridae (e.g., hantavirus), Nairoviridae (e.g., Crimean-Congo hemorrhagic fever [CCHF] virus), Phenuiviridae (e.g., Rift Valley fever virus), and Filoviridae (e.g., Ebola virus, Marburg virus) may cause a characteristic viral syndrome, including fever, headache, myalgias, arthralgias, nausea and vomiting, abdominal pain, and skin manifestations. Severe bleeding, including nasal or GI bleeding, may also occur with some of these viruses. Bleeding into the skin also occurs and results in petechiae, purpura, and ecchymoses.

These viruses are usually found in the tropics, and many are zoonotic, having a rodent (bunyaviruses, arenaviruses) or bat (filoviruses) reservoir or an arthropod vector (flaviruses, most human bunyaviruses), with humans as accidental hosts. Some viral hemorrhagic fevers such as Ebola, Marburg, Lassa, and CCHF viruses are spread from person to person through direct contact with a symptomatic patient or infected body fluids, and some may be spread through the slaughter or consumption of infected animals. Treatment is generally supportive, although the antiviral ribavirin has been useful in some cases, particularly with Lassa fever and CCHF. Preventive measures include rodent vector control and isolating persons infected with viruses for which person-to-person transmission occurs.

Dengue virus is one of the more common hemorrhagic fever viruses and the most prevalent human arboviral infection. It is endemic to the Caribbean, the Americas, Africa, and Southeast Asia. The mosquito vector of dengue, *Aedes* (usually *A. aegypti*), is also found in the southeastern United States, and small outbreaks of locally acquired dengue fever have occurred in Texas, Florida, and Hawaii. It is an acute illness manifested by fevers, severe headache, and muscle aches, the latter giving rise to its nickname, *breakbone fever*. As the fever disappears, a macular rash occurs, which spares the palms and soles and often involves the neck and face (Fig. 33.25). The rash is sometimes described as white islands in a red sea because patches of skin are spared from the rash. The signs and symptoms overlap with those of other infections such as chikungunya. Primary infection is usually benign, but dengue hemorrhagic fever is a severe manifestation of disease that occurs in persons who have been previously infected with a different serotype of the virus; petechiae and purpura are common, as are thrombocytopenia, major hemorrhage, disseminated intravascular coagulation (DIC), and shock. Nucleic acid detection of viremia via PCR is the diagnostic assay of choice, although viral culture can be performed, and serologic testing can confirm the diagnosis in a recovering patient. Treatment for dengue fever is supportive.

Zika virus was first identified in the Americas in March 2015 during an outbreak in Brazil. Prior to this outbreak, cases were seen primarily in Africa and Asia. Signs and symptoms of Zika virus include fever, nonpurulent conjunctivitis, myalgias, arthralgias, headache, and retro-orbital pain. Macular or papular rash, often pruritic, occurs in 90% of infected patients. Subcutaneous bleeding may also be seen with acute infection. Zika virus spread throughout the Americas between 2015 and

Fig. 33.25 Facial rash of dengue fever. (Courtesy Dr. Gail Reid, Loyola University Medical Center, Maywood, IL.)

2016, including locally acquired cases in Florida. It has been associated with microcephaly as well as other neurologic disorders in neonates born from infected mothers. Diagnosis is made serologically or by blood PCR, and there is no specific therapy.

Severe acute respiratory syndrome–coronavirus-2 (SARS-CoV-2)

In December 2019, a new virus was reported in Wuhan, China. It spread rapidly throughout the world and resulted in the global pandemic known as Coronavirus Disease 2019 (COVID-19). The coronavirus that was isolated from infected persons, SARS-CoV-2, infects the respiratory tract and can cause severe pneumonia, and it has been responsible for millions of global deaths. COVID-19 also affects many extrapulmonary organ systems, including the skin. There are a variety of dermatologic manifestations that have been described in patients with COVID-19, including nonspecific maculopapular exanthems, urticaria, erythema multiforme, purpura, and a varicella-like papillovesicular rash. Livedo reticularis, a symmetric lacy pattern of red-blue skin discoloration, may also occur. Chillblain-like lesions (“COVID-toes”) have been noted as a characteristic finding; they typically involve the feet and less commonly the hands. They manifest as painful violaceous plaques and nodules. There is no specific treatment for the skin complications of COVID-19, although topical steroids have been used for certain manifestations such as urticaria.

Parasitic infections

There are three main categories of human parasitic infections: helminthic, protozoal, and ectoparasitic. These infections are usually encountered in tropical and subtropical regions and cause an enormous burden of disease in developing countries. Helminths (derived from the Greek term for “worms”) are

multicellular organisms whose adult stages are typically visible to the naked eye. They are extremely prevalent worldwide, particularly in warm, under-resourced areas of the world and include flatworms (trematodes) and roundworms (nematodes). Protozoa are unicellular organisms that can be free-living or parasitic, and they can infect the blood of humans by arthropod vectors. **Ectoparasites** are organisms that attach to and penetrate the skin and live there, rather than inside the human body. Ectoparasites include fleas, lice, ticks, and mites. Many of these parasitic infections have major or minor dermatologic manifestations as part of the illnesses they cause.

Helminths

Schistosomiasis

Schistosomes are trematode flatworms (flukes). Dermatitis caused by schistosomes is usually seen when the infective larvae of bird and nonhuman mammal schistosomes infect humans. Free-living larvae, or cercariae, that have developed in snails penetrate the skin of humans bathing or swimming in infected waters. These nonhuman schistosomes do not mature in humans and die in the skin. The immune response to the organisms results in a hypersensitivity reaction manifesting as an intensely pruritic, papular eruption known as *cercarial dermatitis*, or *swimmer's itch*. There are many different species of schistosomes that can cause dermatitis depending on the geographic location and host animal. Such infections can be prevalent among bathers in lakes in many parts of the world, including the Great Lakes region of North America and certain coastal beaches. The diagnosis is usually made clinically, although the rash may resemble insect bites or dermatitis as a result of bacteria or allergens. The dermatitis is self-limited. Acute schistosomiasis caused by human schistosomes (Katayama fever) is sometimes associated with a similar pruritic rash related to skin penetration by cercariae. This disease is encountered in Asia, Africa, the Middle East, and South America.

Strongyloides infection

The intestinal helminth *Strongyloides stercoralis* is a nematode found in Southeast Asia, Latin America, Africa, and areas in the southeastern United States. Free-living larvae within soil contaminated by human feces penetrate the skin of humans and may cause a transient dermatitis as they migrate to the vasculature on their way to the lung and then GI tract. Other modes of transmission include solid organ transplantation and oral inoculation (e.g., oral-anal intercourse). In chronic infection, adult *Strongyloides* worms reside in the large intestine and produce larvae that can transform before excretion and autoinfect the host by penetrating the intestine or perianal skin, with the latter resulting in a rash known as *larva currens*. The rash is characteristically migratory (larvae can move 2 to 4 inches per hour), serpiginous, and pruritic. Urticaria may appear, and the buttocks, groin, and thighs are often involved given that the larvae penetrate the skin in the perianal area. *Strongyloides* infection may persist for decades asymptotically or as a mildly symptomatic infection but can evolve into hyperinfection (accelerated autoinfection) and severe disease with dissemination. This is usually seen in persons with immunocompromise. The antiparasitic medication ivermectin is effective treatment.

Filariasis

Filariasis is a nematode infection of tropical and subtropical regions that is transmitted to humans by insect vectors. It is characterized by the involved area of the body: lymphatic filariasis and subcutaneous filariasis (discussed later) and serous cavity filariasis caused by *Mansonella* spp. (not discussed further). These infections can be very disfiguring and debilitating, and this section will focus on the worms that cause most of the lymphatic and subcutaneous forms of disease.

Wuchereria bancrofti, *Brugia malayi*, and *Brugia timori* cause lymphatic filariasis. Larval forms are transmitted by mosquito bites, and they transform into adult worms that reside in the lymph nodes and lymphatic vessels of the legs and male genitalia. Adult worms generally live for 5 to 8 years. *W. bancrofti* is responsible for 90% of cases of lymphatic filariasis and is found in tropical areas worldwide. *B. malayi* is found in Southeast Asia, and *B. timori* is found in southeastern Indonesia.

Lymphatic filariasis often occurs in childhood and is typically asymptomatic for many years, but a minority of patients experience significant obstruction of the lymphatic vessels in the lower extremities and genital region, with resulting so-called *elephantiasis* (Fig. 33.26). Fever and inflammation of associated lymph nodes can occur and may be the result of secondary bacterial or fungal infection; these secondary infections are facilitated by the compromised lymphatic function. The parasites can be found in the bloodstream and are identified by Giemsa or hematoxylin and eosin stain of blood smears that should be obtained at night when parasitemia is greater. More sensitive filarial antigen detection and PCR assays are also available. Diethylcarbamazine is effective in killing microfilariae and the adult-stage parasites and can decrease lymphatic obstruction. Doxycycline also has activity against adult worms; it kills *Wolbachia*, rickettsia-like bacteria that live in symbiosis with adult worms and are required for their survival.

Onchocerca volvulus is transmitted by blackflies and causes subcutaneous nodules and river blindness. Onchocerciasis is a chronic nonfatal disease found in sub-Saharan Africa, Brazil, Venezuela, and Yemen. After transmission by blackflies, the larvae develop into adult worms in subcutaneous tissues, particularly over bony prominences in the head and shoulders, hips, and lower extremities. These subdermal nodules are known as *onchocercomata* (Fig. 33.27). The adult worms live for up to 15 years and shed thousands of microfilariae (larvae), which migrate through the skin and have an affinity for the eye. The most important manifestation of onchocerciasis is *river blindness*, so named because the blackfly vector breeds in fast-flowing rivers or streams, and transmission is highest in rural villages near rivers. River blindness results from larval infiltration of the eye. An inflammatory response occurs on death of the larvae, leading to visual disturbances and blindness. The migration of microfilariae through the skin causes an intensely itchy chronic papular rash and skin edema. Depigmentation or thickening of the skin can occur over time (leopard skin).

Laboratory diagnosis of the cutaneous disease can be made by superficial skin biopsies (skin snips), with specimens usually taken from the skin over the iliac crest or scapulae. Microfilariae can then be demonstrated by microscopic examination of the tissue, although the sensitivity of this method may not be as high as serologic testing or urine testing for filarial antigens. PCR on tissue can be performed if microfilariae are not seen. If cutaneous nodules are present, they can be excised to confirm the presence of adult worms.

Fig. 33.26 Disfiguring lower extremity swelling and marked thickening of the skin caused by lymphatic filariasis (sometimes referred to as elephantiasis). (Courtesy Dr. Gail Reid, Loyola University Medical Center, Maywood, IL.)

Fig. 33.27 Tissue cross-section of a nodule containing *Onchocerca volvulus* microfilariae (hematoxylin and eosin stain, $\times 400$).

Ivermectin kills microfilariae but has a limited effect on adult worms. Because it can therefore control the disease but may not cure it, ivermectin is often given as an initial single dose, with periodic retreatment on a quarterly or yearly basis. This can reduce morbidity and interrupt transmission of the parasite. Doxycycline also appears effective based on its anti-*Wolbachia* activity. *Wolbachia* is an endosymbiotic rickettsia-like bacterium that appears to be required for *O. volvulus* adult worm survival and for embryogenesis.

Dracunculiasis

Dracunculus medinensis, a nematode found in remote areas of Africa, causes guinea worm disease or dracunculiasis. The World Health Organization launched an eradication program in 1980 that has nearly eliminated the disease. The parasite infects humans who drink pond or stagnant river water contaminated with the intermediate host, a copepod or “water-flea” (genus *Cyclops*) that contains guinea worm larvae. After ingestion, the larvae migrate to the small intestine, where they penetrate the intestinal wall and reside in the peritoneal and retroperitoneal

spaces. The worms mature, and female worms migrate to the skin, particularly the legs, where they cause painful blisters and can emerge through the skin. Worm tracks in the skin can develop cellulitis resulting from secondary bacterial infection. The diagnosis is usually obvious when female worms emerge from the skin to release larvae. Treatment involves slow manual extraction of the worm that can be aided by cooling the skin with ice. There is no effective drug therapy.

Hookworm infection

The human hookworms include the nematode species, *Ancylostoma duodenale* and *Necator americanus*, as well as the more recently described *Ancylostoma ceylanicum*, a zoonosis transmissible to humans. These nematode infections vary in geographic location by genus and species but occur predominantly in warm, moist climates and in areas with poor sanitation. Regions of Africa, Asia, the Middle East, and the Americas are endemic for hookworm infection. Eggs are shed into the environment, and infective larvae develop in soil. As with *Strongyloides* infection, walking barefoot or playing on the ground are risk factors. The larvae can quickly penetrate human skin and cause an erythematous, itchy and papular dermatitis known as *ground itch*, particularly in those previously exposed to hookworm. The larvae then pass through the bloodstream into the lungs, are eventually swallowed, and then travel to the intestine, where they develop into adults and remain.

Larvae of the dog and cat hookworms, *Ancylostoma caninum* and *Ancylostoma braziliense*, respectively, can also penetrate the skin of humans but cannot develop further, as humans are accidental hosts. This results in a self-limited dermatitis known as *cutaneous larva migrans* (CLM), or *creeping eruption*. The dermatitis is characterized by larval migration in the skin, with associated serpiginous, elevated tunnels, and indurated, intensely itchy papules and even bullae. The skin lesions can become superinfected with bacteria, like staphylococci and streptococci. The disease is often seen in children who play in sandboxes frequented by cats and dogs, and it is an occupational hazard of workers who crawl or work in areas with damp sandy soil contaminated by dog or cat feces. Spontaneous cure is the rule, although CLM can persist for months or occasionally years. The diagnosis of CLM can be made clinically. Human hookworm infection is diagnosed by microscopic detection of eggs in stool samples. Albendazole and ivermectin are effective treatments for hookworm infection; thiabendazole may also be effective topically for CLM.

Leishmaniasis

Few protozoal infections cause significant skin infection, but *Leishmania* causes a broad spectrum of disease, with cutaneous leishmaniasis being the most common manifestation. Visceral leishmaniasis, known as *kala-azar*, is a severe form of disease seen with certain species (*L. infantum* and *L. donovani*) in which dissemination of parasites to the bone marrow, liver, spleen, or other organs occurs. *Leishmania* is endemic throughout Latin America, Asia, the Middle East, and southern Europe, and in the United States, south-central Texas is an area of endemicity. *Leishmania* is maintained in mammal reservoirs (dogs, rodents, humans) and is transmitted by the bite of sandflies. Human-to-human transmission from mother to child or through transfusion has also occurred.

Most *Leishmania* infections are limited to the skin and adjacent lymph nodes. Cutaneous leishmaniasis develops days to months after the bite of an infected sandfly, often on the head or extremities, and starts as a small, painless papule that enlarges and may ulcerate (Fig. 33.28). Some lesions remain smooth or become hyperkeratotic, and the appearance of the lesions can differ according to the infecting *Leishmania* spp. The lesions often self-resolve in 3 to 18 months, but local dissemination of infection can occur, with development of additional skin lesions in a sporotrichoid or nodular lymphangitis pattern that can enlarge over years. The lesions can mimic a wide variety of other infectious and non-infectious diseases. Immunocompromised patients may have diffuse lesions that can resemble lepromatous leprosy. Mucocutaneous disease can present as destruction of the lips, palate, and nasal septum. Disfiguring scarring and secondary infection can complicate mucocutaneous leishmaniasis.

Identifying *Leishmania* amastigotes (Leishman-Donovan bodies) in a scraping or biopsy of a skin lesion makes the diagnosis; culture and/or PCR assay can also be performed on the tissue. The organism is fastidious, and Novy-MacNeal-Nicolle medium can be used for culture. Serologic testing is also available. As noted earlier, spontaneous cure of cutaneous lesions is typical over a period of months. Treatment can be given to speed healing and prevent scarring, dissemination, and relapse. Pentavalent antimonial compounds (e.g., sodium stibogluconate, meglumine antimoniate) are the most active drugs but are relatively toxic and expensive. Depending on the species of *Leishmania*, fluconazole, ketoconazole, amphotericin, miltefosine, and pentamidine may have activity.

Ectoparasites

Many ectoparasites may cause human infection, including lice (pediculosis), mites (scabies; Fig. 33.29), fleas, flies, ticks, chiggers, and bedbugs. Ectoparasites attach to or burrow in the skin and can remain there for weeks to months. The dermatologic features of these infestations include severe itching and the formation of papules, vesicles, nodules, linear burrows, and excoriations of the skin and scalp. *Sarcoptes scabiei* var *hominis*, the mite that causes scabies in humans, is too small to be seen by the naked eye and burrows in the stratum corneum, laying eggs that hatch and mature in 3 to 4 days. The rash frequently

Fig. 33.28 Facial ulceration caused by *Leishmania* infection.

occurs in multiple skin sites, with an average of 12 mites on an infected individual, predominantly affecting the hands between the fingers, genital region, waist, wrists, elbows, and ankles. The mite avoids areas with a high density of sebaceous glands. Short, linear burrow tracks are classic, but excoriated papules, hyperkeratotic papules, nodules, or plaques may be seen. Patients complain of generalized itching, which can be severe. Crusted (Norwegian) scabies is a particularly severe infestation that occurs in immunocompromised individuals and causes a psoriasis-type dermatitis (Fig. 33.30).

Scrapings of affected areas of skin with visualization of mites, eggs, or feces by microscopy confirms the diagnosis. Skin biopsy can also be performed, with the burrow seen in the stratum corneum. Treatment consists of topically administered lindane, crotamiton, or permethrin. Orally administered ivermectin is usually given for Norwegian scabies or can be considered for patients who fail topical therapy. Treatment is also given to household and sexual contacts, even if asymptomatic.

Lice are blood-sucking insects. Different types of lice cause infestation of different parts of the body; *Pediculus humanus capitis*, *Pediculus humanus corporis*, and *Phthirus pubis* cause head, body, and pubic infestations, respectively. Lice infestations are also known as *pediculosis* and *phthiriasis*. Body and head lice are similar in appearance: 2 to 3 mm in length, 3 pairs of legs, and tan-gray in color. Lice are transmitted by direct head-to-head contact, with fomites such as brushes or combs less important in transmission because of the short lifespan of lice removed from the body. Transmission of body lice is facilitated by poor hygiene and, as noted earlier, body lice can transmit infection such as typhus, *B. quintana*, and relapsing fever. Intense itching and local erythema, papules, and excoriations of the skin characterize the infection.

The diagnosis is made by identifying live lice (Fig. 33.31) and nits (eggs), although lice move quickly and avoid light. Topically administered permethrin, malathion, and lindane have traditionally been used, although lindane can be associated with neurotoxicity, and resistance to permethrin, the most widely used head louse agent, has been noted. Anthelmintics such as ivermectin (oral or topical administration) or albendazole may be given for severe infestations.

Immune- or toxin-mediated dermatologic manifestations of infectious agents

As described earlier, many different local and systemic infections caused by bacteria, fungi, viruses, and parasites produce diseases of the skin. Skin lesions resulting from direct cutaneous infection and those resulting from hematogenous spread to the skin have been described. Additional dermatologic manifestations of infection can result from the body's immune response to the infecting organism or from toxin production by the organism.

Immune-mediated cutaneous disease

Disseminated intravascular coagulation

Dysregulation of the blood coagulation system frequently occurs during sepsis from any cause and, when severe, can lead

Fig. 33.29 A, *Sarcophaga scabiei* adult showing short legs and conical spines (unstained, $\times 400$). B, Tissue cross-section of scabies lesion showing larvae burrowed into the epidermal layer of the skin (hematoxylin and eosin stain, $\times 400$).

Fig. 33.31 Parasite, pubic hair from surgical patient, unstained mount ($\times 400$). Three pairs of legs are identified with characteristic claws at the tips. Morphology consistent with *Phthirus pubis* (crab louse). Impression: louse infestation.

to DIC that manifests as bleeding and thrombosis. Important mediators in this process are macrophages and neutrophils; the former recognize invading pathogens and initiate the coagulation cascade, and activated neutrophils release proinflammatory substances leading to neutrophil adhesion, platelet aggregation, and damage to endothelial cells. Leukocyte-platelet aggregation and fibrin deposition in blood vessels is the hallmark of

sepsis-associated DIC. Damaged cells then release other factors that are procoagulants. Thrombi develop in organs such as the liver, lungs, brain, and kidneys, resulting in petechiae of the skin (Fig. 33.32), thrombocytopenia, bleeding, and multiorgan dysfunction. Bacterial sepsis, such as that caused by *Neisseria meningitidis*, streptococci, or enteric gram-negative organisms, is the most common setting in which to encounter infection-related DIC, but it can occur with other types of pathogens, such as the hemorrhagic fever viruses.

COVID-19 is often associated with thrombotic events via activation of the coagulation cascade, intravascular inflammation, and endothelial damage, similar to DIC. However, thrombocytopenia is less often seen in COVID-19, at least early in infection, and prolongation of prothrombin time (PT) is usually minimal. When thrombocytopenia and prolonged PT do occur in patients with COVID-19, patient outcomes appear to be poorer. The mechanisms for COVID-19-induced coagulopathy are still under investigation.

An additional skin manifestation of DIC is purpura fulminans. This syndrome has typically been associated with meningococcemia, but it has also been linked to septicemia with *S. aureus*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*. It is characterized by rapidly developing skin hemorrhage, skin necrosis, and peripheral gangrene accompanied by shock syndrome. Death or amputation often results.

Vasculitis

Many types of infections can trigger direct or indirect immune-mediated damage to small blood vessels in dermal tissues, resulting in palpable purpura, a vasculitic skin lesion typically involving the lower extremities. Infection causes about 20% of cutaneous vasculitis, and it typically results from circulating immune complexes (formed by microbial antigens bound to antibodies) that become trapped in the small vessels of the skin. Cutaneous vasculitis has been associated with bacterial, fungal, viral, protozoal, and helminthic infections. Hepatitis B virus, hepatitis C virus, adenovirus, parvovirus, herpesviruses, streptococci, staphylococci (Fig. 33.33), *Legionella*, rickettsiae, and *Yersinia* are some of the organisms more commonly described as causing vasculitis. Hepatitis C virus can also be associated with a cutaneous vasculitis caused by the production of cryoglobulins, immunoglobulins that precipitate in cold temperatures.

Fig. 33.32 Petechial lesions in meningococcemia.

Infection-related, immune complex-induced cutaneous disease is often seen in endocarditis, with cutaneous purpura the most common skin manifestation. In addition, painful, small skin nodules located on the pads of the fingers and toes and on the thenar eminence, known as *Osler nodes*, may be seen. Traditionally they were thought to be caused by the deposition of immune complexes in soft tissues, although it has also been reported that they are actually microabscesses from small emboli to the skin, similar to Janeway lesions. Janeway lesions are flat, painless hemorrhagic macules located on the palms and soles. Bacteria can be cultured from biopsy specimens from Janeway lesions and have been isolated from Osler nodes. Staphylococci and streptococci are typically associated with these skin manifestations, although gram-negative bacteria and *Candida* may produce similar lesions.

Toxin-mediated cutaneous disease

Certain bacteria, particularly staphylococci and streptococci, can produce toxins that affect the skin, resulting in distinct clinical syndromes. These infections may start as primary skin and soft tissue infections or may initially affect another site, with subsequent involvement of the skin caused by the effects of circulating toxin.

Staphylococcal scalded skin syndrome

Certain strains of *S. aureus* can produce exfoliative toxins that result in staphylococcal scalded skin syndrome (SSSS), a blistering skin condition most commonly seen in children younger than 5 years of age. SSSS is characterized by fever, skin tenderness, and a scarlatiniform rash (resembling the rash of scarlet fever; see later), followed by extensive formation of bullae and exfoliation like that seen in burn patients. SSSS sometimes occurs in adults, particularly those with underlying illness such as renal disease, cancer, IV drug use, HIV, or diabetes mellitus. The toxins act exclusively on the stratum granulosum of the epidermis and thus do not affect mucosal tissues. The Nikolsky sign, separation of the epidermal layer on gentle stroking, is characteristic. Large flaccid blisters form and rupture, causing the skin to denude and peel off in sheets, leaving areas of bright red underlying skin exposed. Secondary bacterial infection and fluid loss can occur, but the skin generally heals without scarring. Nosocomial epidemics

Fig. 33.33 Hemorrhagic vasculitic lesions of *Staphylococcus aureus* endocarditis.

of SSSS have been reported in newborn nurseries. SSSS treatment involves the administration of antimicrobial agents, hydration, and local wound care.

Toxic shock syndrome

Cutaneous desquamation occurs in **toxic shock syndrome** (TSS) caused by the production of staphylococcal exotoxins. These include a unique group of exotoxins that are referred to as *superantigens* because of their ability to cause widespread non-antigen-specific activation of T lymphocytes. Superantigens include toxic shock syndrome toxin 1 (TSST-1), staphylococcal enterotoxins, and streptococcal pyrogenic exotoxins (SPEs). The activation produced by these superantigens results in the rapid release of cytokines by lymphocytes and macrophages. Originally described in children with fever, sore throat, scarlatiniform rash, and desquamation by Todd in 1978, TSS subsequently gained notoriety in 1980 when a number of cases were reported among menstruating women who had used superabsorbent tampons. The tampons apparently provided an environment favorable for TSST-1 production.

Nonmenstrual TSS can occur in many different settings. It has been described in postpartum, after influenza infection, and in association with surgical wound infections and contaminated nasal packing in patients with nosebleeds. Menstrual and nonmenstrual TSS have similar clinical presentations; a diffuse sunburn-like erythroderma appears early in the course and is accompanied by fever, hypotension, and evidence of multiorgan dysfunction. Desquamation of the skin, especially on the palms and soles, occurs during the convalescent stage of the illness. Blood cultures may be positive for *S. aureus*, and staphylococci may be cultured from the initial site of infection. Treatment includes antimicrobial therapy and supportive care with hydration, vasopressors, and debridement of any infected tissue. IVIG may be helpful, presumably through neutralizing the activity of superantigens. Recurrences have been described in as many as 30% to 40% of cases.

Streptococcal TSS caused by GAS (*S. pyogenes*) was increasingly noted in the late 1980s and early 1990s, with the resurgence of invasive and complicated streptococcal infections. Like its staphylococcal counterpart, streptococcal TSS may occur whenever exotoxin-producing strains of GAS infect or

colonize the skin or mucous membranes, particularly strains producing SPEs, although other exotoxins have been implicated. Most streptococcal TSS cases have been in young, otherwise healthy adults, and it is thought that lack of protective immunity is a risk factor. The portal of entry is typically the skin with cellulitis that progresses rapidly, although many invasive streptococcal infections do not have a recognized portal of entry. The subsequent clinical signs and symptoms of GAS TSS are like those of staphylococcal TSS. Blood cultures are more often positive in streptococcal TSS than in staphylococcal TSS. Treatment is with antimicrobial therapy, debridement of infected tissues, and supportive measures. IVIG may be a useful adjunctive therapy.

Scarlet fever

Scarlet fever is a form of GAS disease that can occur when the infecting strain produces SPEs. It occurs mostly in children, concomitantly with pharyngeal infection, although it can also be seen with infections at other sites. Fever is typically present, and the rash starts on the chest and spreads outward. The red, sandpaper-textured rash is often better felt than seen and appears most often on the neck and chest and in skin folds. Typically, the rash does not involve the face, but there is a flushing of the skin, with circumoral pallor, and the patient may have a strawberry tongue (a bright red tongue with dots of white papillae). During convalescence, desquamation of the skin occurs, especially on the hands and feet. The diagnosis is usually made clinically; treatment is with antimicrobials such as penicillins, macrolides, or cephalosporins.

Laboratory diagnosis

A variety of diagnostic methods may be helpful in determining the cause of skin and soft tissue infections. Frequently, primary care providers will swab the surface of broken or ulcerated skin for Gram stain and culture. However, this technique provides little clinically useful information. Swabs of surface wounds or skin are likely to yield colonizing or contaminating bacteria, and there is a lack of correlation between surface colonization and below-the-surface infection. Swabs may also lead to false-negative Gram-stained smears and cultures for several reasons: they may not absorb enough material for culture, organisms may adhere to the swabs rather than being released into culture media, and bacteria do not survive as well on a swab as they do within fluid or a tissue sample. Therefore deep aspirates or biopsies of involved tissue are generally much more informative. For example, if pustules or vesicles are present, the roof or crust should be removed with a sterile blade, and any pus or exudate should be Gram stained and cultured. It is possible to obtain a specimen in a patient with cellulitis by injecting a small amount of preservative-free, physiologic saline into the advancing margin of the affected skin, aspirating it, and then culturing the fluid that is withdrawn. Alternatively, a punch biopsy of the advancing margin can be performed and submitted for Gram stain and culture.

In addition to smear examination and culture of the affected site, exuded pus should always be examined for the

presence of granules and branching filaments suggestive of infection by actinomycetes or fungi. Smears prepared from exudative material and subsequently Gram stained may show the presence of inflammatory cells and characteristic morphologic bacterial or fungal forms that may lead to an initial diagnosis. However, examination of a Gram-stained smear is relatively insensitive for detecting bacteria, and culture is still the best clinically available method of diagnosing cutaneous infections. It is also important to note that organisms may not appear the same on a Gram-stained smear of tissue as they do in pure culture; staphylococci, for example, may not be found in clusters, and streptococci may not form chains.

In addition to Gram stain, it may be appropriate to perform a wet mount with the addition of potassium hydroxide to enhance the appearance of fungi that may be present. Calcofluor white stain may also be used when fungal infections are suspected; yeasts and molds fluoresce and are more readily seen. In addition, if mycobacterial disease is suspected, a Ziehl-Neelsen or Kinyoun acid-fast stain may be performed. Fluorescent stains (rhodamine and auramine dyes) are also available that bind mycobacterial cell walls and are a more sensitive method of staining mycobacteria. To identify *Nocardia* species, a modified acid-fast stain can be performed, using a weaker decolorizing agent than the acid-fast stains. As noted in the “Herpesviridae” section earlier in this chapter, certain viral pathogens such as HSV and VZV can be detected rapidly by obtaining scrapings of new vesicular or ulcerated lesions and performing a DFA test on the specimen to detect viral antigens.

Infectious agents are recovered in routine culture using primary nonselective media, such as blood and chocolate agars, and selective media. MacConkey agar is a selective medium designed to culture nonfastidious gram-negative bacilli and identify those that ferment lactose; phenylethyl alcohol and colistin–nalidixic acid are selective media that preferentially grow gram-positive organisms. For the growth of anaerobic organisms, samples must be collected from infected tissue and transported using an anaerobic transport medium to maximize recovery. Because many anaerobic infections are polymicrobial, samples must be inoculated on culture media that are selective for gram-positive and gram-negative bacteria. Ranges of pH, temperature, oxygen levels, and nutrients are required for the growth of various types of organisms. Therefore communication between the primary care provider and microbiology laboratory is essential for optimizing the information obtained from a clinical specimen.

Case check 33.3

In necrotizing soft tissue infections, cultures are best obtained from purulent discharge or deep tissue biopsy samples rather than by swabbing the surface of a wound. Gram-stained smears from infected tissue in diabetic soft tissue infections may show inflammatory cells and mixed gram-positive and gram-negative bacterial populations. Collection of pus and tissue specimens for culture from diabetic foot infections should also allow the recovery of anaerobic bacteria, which are often present. The microbiology laboratory can identify polymicrobial infections that are often present in diabetic wounds by using various culture media.

Once organisms are growing in culture, identification of isolates is performed using a variety of methods, some of which may be automated. A Gram stain provides the microscopic characteristics of bacterial organisms growing in culture, and further information is obtained from the appearance of the bacterial colonies on laboratory media. Biochemical tests can help identify the organism, while MALDI-TOF mass spectrometry has been increasingly employed in many laboratories. This technique takes advantage of the unique protein profiles of organisms. Assayed sample results are compared with a database for identification. MALDI-TOF mass spectrometry is more accurate than conventional biochemical phenotypic testing traditionally used in clinical microbiology laboratories and can give results in minutes.

Antimicrobial susceptibility testing is subsequently performed on isolates when the susceptibility cannot reliably be predicted based on the organism's identity. For example, GAS have been uniformly susceptible to penicillin, so antimicrobial testing of these organisms is generally presumed unnecessary. Standards have been published and are updated regularly on the performance and interpretation of antimicrobial susceptibility testing based on the correlation of testing results with clinical outcomes. In some cases, there are inadequate data on which to define the drug concentrations at which certain organisms are susceptible to various antimicrobials, particularly for unusual or fastidious organisms.

Other media and techniques are used to culture nonbacterial organisms. *Candida* spp. will grow on blood agar plates, but SDA is a selective fungal medium that has an acidic pH, which is preferred for optimizing fungal growth and suppresses the growth of some bacteria. Lowenstein-Jensen and Middlebrook media are solid media that support the growth of mycobacteria. Certain mycobacteria such as *M. chelonae* and *M. abscessus* grow quickly in culture, but more slowly growing species such as *M. tuberculosis* may take as long as 8 weeks to grow. Studies have demonstrated that mycobacteria grow more quickly in liquid media, allowing the detection of *M. tuberculosis* in as early 1 to 2 weeks.

Nucleic acid probes are available for several of the mycobacterial species, including *M. tuberculosis*, and these can make an identification to the species level once growth is present on a solid medium. Nucleic acid amplification tests (NAATs) are now playing a significant role in the diagnosis of tuberculosis. Commercially available NAAT assays can identify *M. tuberculosis* directly from sputum with a sensitivity that is greater than staining for the bacilli but lower than culture. NAATs can also identify mutations that confer resistance to first-line mycobacterial antibiotics such as isoniazid and rifampin.

Because viruses are intracellular pathogens, they cannot be cultured using the same techniques as for bacteria and fungi and require living cells for isolation (cell culture). If viral culture is desired, specimens should be transported in a special viral transport medium that contains antimicrobial agents to suppress the growth of nonviral organisms. After inoculation of the specimen into a cell culture, the presence of virus is revealed by the observation of a cytopathic effect or a lysing of the cells and separation from the tissue culture substrate. The identity of the virus can then be confirmed by the addition of specific fluorescent antibodies directed against various

viruses or related immunoassay techniques. Because of the cost, technical expertise, and time, most clinical laboratories have replaced cell culture methods with antigen detection assays and NAATs.

Several other non-culture-based techniques for the detection of pathogens that may cause skin infection exist. These include urine antigen detection (e.g., for systemic fungi); serum antibody tests for bacteria, viruses, and parasites; and PCR assays on blood or tissue for the detection of a great variety of bacteria, fungi, and viruses. In addition, multiplex PCR assays are available to simultaneously detect a panel of potential pathogens in blood, respiratory specimens, or stool. For example, the BioFire FilmArray blood culture identification 2 (BCID2) panel (BioFire Diagnostics) extracts nucleic acids from the blood, uses PCR to amplify nucleic acids, and tests for a variety of bacteria and fungi in one test, with results in approximately 1 hour. Pathogens such as *Listeria monocytogenes*, *S. aureus*, *S. pyogenes*, *E. coli*, *P. aeruginosa*, and *Candida* spp. can be detected by this assay. The BCID2 panel can also detect the *mecA* gene that confers methicillin resistance (e.g., in *S. aureus*), the *vanA* and *vanB* genes that confer vancomycin resistance (e.g., in *Enterococcus*), and genes in gram-negative organisms that confer resistance to certain beta-lactam and carbapenem antibiotics (e.g., CTX-M, KPC, NDM). This allows rapid determination of antimicrobial resistance and quicker implementation of appropriate therapy.

POINTS TO REMEMBER

- The skin, skin structures, and normal microbiota play a significant role in protecting the host against microbial invasion and disease.
- The normal skin biota can be involved in the pathogenesis of skin and skin structure infections, particularly if the integrity of the skin is compromised.
- There is an extensive variety of skin and soft tissue infections, which can be classified according to the type of skin lesion produced, the causative organism, or the pathogenesis of the infection (e.g., as a primary entity or secondary to a preexisting infection or systemic manifestation).
- Bacteria, viruses, fungi, and parasites are all important causes of skin and soft tissue infections and diseases.
- *S. aureus* and *S. pyogenes* are common causes of pyoderma.
- Virulence factors of disease-producing organisms (e.g., toxins) can enable the organisms to evade host defense mechanisms, which can result in severe manifestations of infection.
- A compromised immune system can lead to more severe or unusual manifestations of infection and can allow normally innocuous organisms to be pathogenic.
- The occurrence of disease in a host is a function of the underlying host's immunity and virulence of the pathogen.
- Proper specimen collection, correct timing in collection of the clinical specimen, proper laboratory processing of specimens, and clinical context are all important factors to consider when distinguishing between colonization and infection by microorganisms and in making an accurate diagnosis.

LEARNING ASSESSMENT QUESTIONS

1. A hospitalized patient receiving total parenteral nutrition develops candidemia. How is the skin involved in the pathogenesis of this infection?
2. How do folliculitis, furuncles, and carbuncles differ in their pathophysiology and appearance?
3. What are the typical organisms found in diabetic foot infections and gangrene?
4. What is a zoonotic disease, and what are some of the zoonoses that cause skin and soft tissue infection?
5. A patient who has recently received chemotherapy and radiation therapy for a bone marrow transplant develops necrotic skin lesions. A culture from a biopsy of the lesion grows a mold. Which fungi may cause these lesions?
6. Which of the common childhood viral infections are lifelong and can manifest themselves in adults after a period of latency?
7. What are the causes of swimmer's itch, creeping eruption, and ground itch?
8. Which bacteria produce cutaneous manifestations because of toxin production?
9. Which organisms are characterized by the formation of granules and branching filaments in wound exudates?
10. What are some important principles of the laboratory diagnosis of skin and soft tissue infection?
11. A 55-year-old male patient acquired a severe soft tissue infection while working on his boat. The patient has a history of alcohol abuse and hepatitis. Exudates are sent to the microbiology laboratory for Gram stain smear and culture. The culture grows oxidase-positive, fermenting, curved, gram-negative bacilli on sheep blood agar but requires NaCl for growth. Which organism would you suspect?
 - a. *Vibrio vulnificus*
 - b. *Aeromonas hydrophila*
 - c. *Clostridium perfringens*
 - d. *Streptococcus pyogenes*
12. Which of the following conditions is an abscess that extends more deeply into the subcutaneous tissue and may have multiple draining sites?
 - a. Furuncle
 - b. Carbuncle
 - c. Necrotizing fasciitis
 - d. Folliculitis
13. Which condition causes the nail margin to become painful, red, warm, and swollen with pus?
 - a. Furuncle
 - b. Carbuncle
 - c. Eschar
 - d. Paronychia
14. A 5-year-old male patient presents at the family health center with multiple areas of superficial skin loss resembling scalded skin. Cultures from the area show no growth, but nasal cultures yield colonies of catalase-positive, gram-positive cocci. Which organism would you suspect?
 - a. *Streptococcus pyogenes*
 - b. *Streptococcus agalactiae*
 - c. *Staphylococcus aureus*
 - d. *Pseudomonas aeruginosa*
15. A patient presents with an infection that developed after skinning his kill on a deer hunting trip. The patient had minute cuts on the hands that likely acted as ports of entry for organisms. Which condition would you suspect?
 - a. Tularemia
 - b. Plague
 - c. Anthrax
 - d. Melioidosis
16. Catalase negative, beta-hemolytic colonies are isolated from a wound culture taken from a 2-year-old female patient who presented with fluid-filled vesicles on her face. The lesions are characterized as painful, and the areas of inflammation are indurated with raised borders that are sharply demarcated from the adjacent normal skin. Which condition would you suspect?
 - a. Scarlet fever
 - b. Bullous impetigo
 - c. Erysipelas
 - d. Erysipeloid
17. A rancher shows some characteristic lesions on his face described as black scabs. The organisms recovered from culture are gram-positive large rods that are aerobic and produce non-hemolytic, non-motile colonies. Which organism would you suspect?
 - a. *Bacillus anthracis*
 - b. *Nocardia asteroides*
 - c. *Actinomyces israelii*
 - d. *Francisella tularensis*
18. An aspirate from a lesion is taken from a butcher who saw his physician 4 days after infecting his finger while trimming pork products. The infected lesion is sharply defined, painful, and swollen with a purplish red zone. The Gram-stained smear from the culture shows gram-positive small rods. Based on this information, which condition would you suspect?
 - a. Tularemia
 - b. Plague
 - c. Anthrax
 - d. Erysipeloid
19. Which organism is a common cause of eumycetoma?
 - a. *Actinomyces* sp.
 - b. *Madura* sp.
 - c. *Streptomyces* sp.
 - d. *Aspergillus* sp.
20. Which disease results from reactivation of the varicella-zoster virus that presents as vesicular eruption in a unilateral dermatomal distribution?
 - a. Shingles
 - b. Chickenpox
 - c. Rubella
 - d. Measles

Treatment and prevention of diarrhea, 886

Bibliography, 888

4. Determine the factors that place individuals at risk of gastrointestinal infection.
5. Justify the importance of obtaining a medical and travel history in patients presenting with gastrointestinal tract signs and symptoms.
6. Describe the various diarrheagenic *Escherichia coli* strains including their virulence mechanisms.
7. Compare infectious diarrhea in the immunocompromised patient with that in an immunocompetent patient.
8. Identify the common causes of traveler's diarrhea.
9. For each of the bacterial agents described, correlate the predicted results of direct microscopy of the stool specimen, and recommend the selective media for the maximal recovery of the pathogen.
10. Differentiate the clinical manifestations in diarrheal illnesses caused by chemical toxic agents in food poisoning from those mediated by enteric pathogens.
11. Describe modes of treatment and preventive measures of diarrheal events.

KEY TERMS

Achlorhydria

Cholera

Ciguatera

Enterotoxin-mediated diarrhea

Enteric fever

Fecal leukocytes

Median infectious dose (ID₅₀)

Opportunistic pathogens

Orthostatic changes

Scombroid

Traveler's diarrhea

Toxic megacolon

Case in point

A 32-year-old healthy male patient from the United States was visiting his family in a small village in Mexico. The patient consumed some of the local food and drank the water. Four days after arriving in Mexico, he experienced a sudden onset of diarrhea. The diarrhea occurred more than 10 times the first day and was accompanied by nausea, with several episodes of loose, watery stool. The stool contained no gross blood, pus, or mucus. The patient was afebrile but complained of crampy abdominal pain with watery diarrhea and dizziness when standing. His heart rate was rapid, 120 beats/minute (reference range 60 to 100 beats/minute).

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Explain the normal host defenses at each level of the gastrointestinal tract in preventing infection.
2. Describe the major mechanisms whereby bacteria can cause diarrhea.
3. Associate the onset of symptoms, food ingested, travel history, and clinical manifestations with the possible cause of diarrheal illness.

Issues to consider

After reading the patient's case history, consider:

- The travel, food and water intake, and medical history of the patient
- Clinical symptoms at the time of presentation, and the duration and time of onset of symptoms
- Possible sources of infection

Acute diarrheal illness is one of the most common problems evaluated by health care providers. Colorful names such as *Montezuma's revenge*, *Delhi belly*, *Greek gallop*, *Rome runs*, *Aztec two-step*, and *back door sprint* are evidence of the universal prevalence of acute diarrheal illness across the globe. Acute diarrhea has a significant burden on morbidity and mortality worldwide. In 2018, the Centers for Disease Control and Prevention (CDC) estimated that 48 million people become ill, 128,000 are hospitalized, and 3000 die from foodborne diseases each year in the United States.

Worldwide, diarrhea is responsible for the deaths of 2195 children per day. This is about 1 in 9 child deaths worldwide, making diarrhea the second leading cause of death among children younger than 5 years of age. This is more than human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS), malaria, and measles combined.

Although most healthy people experience a self-limiting illness lasting only a few days, others can experience chronic symptoms, bacteremia, dehydration, and serious sequelae such as malnutrition, severe dehydration, and death. Identifying those individuals who require early treatment is key to limiting morbidity and death. This chapter reviews host and pathogen factors that lead to illness; presents a clinical and laboratory approach to making the diagnosis; discusses common bacterial, viral, and parasitic pathogens; and summarizes treatment and prevention strategies.

Case check 34.1

There are many epidemiologic clues that can provide information regarding the cause of this patient's diarrhea, including his recent travel history to Mexico, dietary history, and health status. The patient is not immunocompromised, there is no evidence of inflammation, and he does not have fever or blood, pus, or mucus in the stool.

The differential diagnosis of acute diarrheal illness is among the broadest in medicine. The chronicity of disease may help narrow the differential diagnosis. A variety of viral, bacterial, and parasitic pathogens may be involved. Toxin-mediated disease may be the cause of diarrhea, and numerous noninfectious causes exist, such as laxative use, tumors, malabsorption, inflammatory bowel disease, and problems with motility caused by hyperthyroidism, irritable bowel syndrome, or surgical reduction of the gut. Evaluating all patients for all possible causes of diarrhea would be prohibitively expensive, so clinical clues must play a role in guiding the most efficient diagnostic testing. The health care provider should determine the most appropriate workup to limit morbidity and death for the patient and prevent transmission of the infection to others.

Anatomic considerations

Although there are exceptions, diarrheal pathogens are usually acquired by ingesting a contaminated food or beverage. Fig. 34.1 shows a diagram of the GI tract. There are host defenses against infection at many levels. Most pathogens that are ingested never reach the intestinal tract because of the acidic environment of the stomach. Normal gastric pH is 1.6 and kills more than 99.9% of coliform bacteria within 30 minutes. Some pathogens, however, are resistant to gastric acids, most notably the cyst phase of parasites and bacterial spores.

The small intestine has a different mechanism to prevent infection. It is constantly in motion (peristalsis). Organisms that rely on adhering to the intestinal wall to cause infection may be hampered by the peristaltic movements. The small intestine and colon have lymphoid tissue that produces antibody, primarily immunoglobulin A (IgA), which may have some effect against pathogenic organisms. The host's normal gut biota is large, with an estimated 10^6 organisms of normal biota per gram of fecal material. Most of these bacteria are anaerobic and outnumber the facultative aerobic bacteria by a factor of

Table 34.1 Microbiota found in the large intestine

Bacterial species ^a	Incidence (%)
Strict anaerobes	
Gram-negative	
<i>Bacteroides fragilis</i>	100
<i>Bacteroides</i> spp.	100
<i>Fusobacterium</i> spp.	100
<i>Prevotella copri</i>	Common
Gram-positive	
Lactobacilli	20–60
<i>Clostridium perfringens</i>	25–35
<i>Clostridium</i> spp.	1–35
<i>Peptostreptococcus</i> spp.	Common
<i>Peptococcus</i> spp.	Common
Facultative anaerobes	
Gram-positive cocci	
<i>Staphylococcus aureus</i>	30–50
<i>Enterococcus</i> spp.	100
β-Hemolytic streptococci, groups B, C, F, and G	0–16
Gram-negative bacilli (Enterobacterales)	
<i>Escherichia coli</i>	100
<i>Klebsiella</i> spp.	40–80
<i>Enterobacter</i> spp.	5–55
<i>Proteus</i> spp.	3–11
<i>Pseudomonas aeruginosa</i>	3–11
Yeast	
<i>Candida albicans</i>	15–30

^aStrict anaerobes are present in ratio of 1000:1 with facultative aerobes.

Fig. 34.1 Anatomy of the gastrointestinal tract.

1000:1. Table 34.1 lists the microorganisms frequently found in the large intestine. These established organisms compete with potential pathogens for nutrients and for places to attach to the colon wall. The normal host biota can also produce substances toxic to potential pathogens (e.g., bacteriocins).

Several factors determine the risk of being infected with a GI pathogen. The first is the **median infectious dose (ID_{50})**, the number of organisms that must be ingested to cause a diarrheal illness in 50% of exposed individuals. Even with the best defenses, if an overwhelming number of organisms are ingested, disease can occur. The second factor relates to the host defenses discussed earlier. Patients with inadequate stomach acidity (**achlorhydria**, the absence of hydrochloric acid in gastric secretions), whether primary or because of medications (e.g., proton pump inhibitors that can dramatically alter gastric pH), are more likely than individuals with normal gastric acidity to become ill. Antimicrobial exposure alters the normal biota of the colon and predisposes one to infection with enteric pathogens.

Approach to diagnosis of the patient with diarrhea

The cause of diarrhea can usually be determined by the history, physical examination, and laboratory analysis of a stool

specimen. Table 34.2 summarizes some of the common pathogens involved in diarrhea and the relative frequency of fever, nausea and vomiting, bloody diarrhea, and fecal evidence of inflammation.

History

Diarrhea is defined as an “alteration in a normal bowel movement characterized by an increase in the water content, volume, or frequency of stools.” Most epidemiologic investigations use a definition of more than three bowel movements per day as a definition of diarrhea. The first step in evaluating an individual presenting with an acute diarrheal illness is to take a detailed history and perform a thorough physical examination. Most infections are acquired by ingesting the microorganism. Thus a carefully taken travel and dietary history can point to a causative diagnosis and direct the microbiologic workup.

Group exposures help identify outbreaks in the community, and the history should document if other individuals in contact with the patient have also become ill. Recent travel history is important because travelers to underdeveloped areas are at risk for different types of infections. Recreational activities, such as hiking or backpacking, and even swimming in public pools, have been associated with outbreaks of infectious diarrhea. Seasonality, daycare attendance, and living conditions are also epidemiologic clues to an infectious cause

Table 34.2 Common pathogens involved in diarrhea

Pathogen	Fever	Nausea, vomiting	Bloody stool	Fecal inflammation
<i>Campylobacter</i> spp.	Common	Occurs	Occurs	Common
<i>Salmonella</i> spp.	Common	Occurs	Occurs	Common
<i>Shigella</i> spp.	Common	Common	Occurs	Common
Enterohemorrhagic <i>Escherichia coli</i>	Atypical	Occurs	Common	Often not found
<i>Clostridioides difficile</i>	Occurs	Not characteristic	Occurs	Common
<i>Yersinia enterocolitica</i>	Common	Occurs	Occurs	Occurs
<i>Entamoeba histolytica</i>	Occurs	Variable	Variable	Variable
<i>Cryptosporidium</i> spp.	Variable	Occurs	Not characteristic	None to mild
<i>Cyclospora</i>	Variable	Occurs	Not characteristic	Not characteristic
<i>Giardia duodenalis</i>	Not characteristic	Occurs	Not characteristic	Not characteristic
Viruses	Variable	Common	Not characteristic	Not characteristic

Modified from Thielman N. M., & Guerrant, R. L. (2004). Clinical practice. Acute infectious diarrhea. *The New England Journal of Medicine*, 350, 38.

of diarrhea. All of these historic factors must be considered when evaluating a patient with gastrointestinal (GI) disease.

Other key questions that can be asked include the following:

- What is the duration of symptoms? Acute diarrhea is generally defined as symptoms lasting fewer than 14 days. If symptoms last longer than 14 days, the term *persistent diarrhea* is sometimes used. When diarrhea lasts longer than 30 days, the term *chronic diarrhea* is applied. These categories can help narrow the differential diagnosis because many causes of diarrhea are self-limiting.
- Are there associated symptoms of inflammation? Fever, bloody stools, and tenesmus can be symptoms of a more invasive process.
- Does the patient have a history of previous GI symptoms? A positive history may suggest other illnesses, such as inflammatory bowel disease or irritable bowel syndrome, rather than an infectious cause.
- Does the patient have an underlying illness? For example, patients with AIDS or who are immunosuppressed because of chemotherapy or organ transplantation are at risk for organisms not routinely considered pathogens in otherwise healthy individuals.
- Is the patient taking any medications? Some medications (e.g., several common antidepressant medications, medications for HIV infection) are known to cause GI side effects. A recent history of antimicrobial use may also suggest an infection with *Clostridioides difficile*.

Travel to countries with less effective sewage facilities increases the risk of acquiring an enteric pathogen. **Traveler's diarrhea** is usually caused by enterotoxigenic *Escherichia coli* (ETEC). This disease has a short incubation period (usually between 5 and 15 days after arrival) and normally lasts from 1 to 5 days. If a diarrheal illness develops weeks after a traveler returns home, a parasitic infection such as *Giardia duodenalis* (synonyms *G. lamblia* and *G. intestinalis*) or *Entamoeba histolytica* infection would be more likely.

Because most diarrheal pathogens are acquired by ingesting a contaminated food or beverage, a detailed food history going back 3 days before the onset of symptoms is helpful. Water, unpasteurized milk, poultry, beef, and shellfish are

Table 34.3 Common food vehicles for specific pathogens or toxins

Vehicle	Pathogen or toxin
Undercooked chicken	<i>Salmonella</i> spp., <i>Campylobacter</i> spp.
Eggs	<i>Salmonella</i> spp. (especially <i>S. Enteritidis</i>)
Unpasteurized milk	<i>Salmonella</i> , <i>Campylobacter</i> spp., <i>Yersinia</i> spp.
Water	<i>Giardia duodenalis</i> , noroviruses, <i>Campylobacter</i> spp., <i>Cryptosporidium</i> spp., <i>Cyclospora</i>
Fried rice	<i>Bacillus cereus</i>
Fish	
Shellfish	<i>Vibrio cholerae</i> , <i>V. parahaemolyticus</i> , <i>V. vulnificus</i> , other <i>Vibrio</i> spp., neurotoxic shellfish poisoning, paralytic shellfish poisoning, noroviruses, and sapoviruses
Tuna, mackerel, mahi-mahi	Scombroid poisoning
Grouper, amberjack, snapper	Ciguatera
Sushi	<i>Anisakis</i> spp.
Beef, gravy	<i>Salmonella</i> spp., <i>Campylobacter</i> spp., <i>Clostridium perfringens</i>

Modified from Goodman, L. J. (1993). Diagnosis, management, and prevention of diarrheal diseases. *Current Opinion in Infectious Diseases*, 6, 88.

often responsible for causing foodborne infections. **Table 34.3** lists foods that are commonly linked to infectious diarrhea and the organisms that are typically involved. The duration of illness can also be helpful in narrowing the differential diagnosis. Patients with an invasive bacterial pathogen and bloody stools usually present earlier than patients with *Giardia* or other parasitic infections. Some patients with toxin-mediated illness may present very early in the course of symptoms or never present to a clinician because of the relatively brief course of these illnesses. If the patient is currently taking or has recently received antimicrobial agents, *C. difficile* would be an important consideration.

The patient should be asked about other medical conditions because diarrhea can be caused by noninfectious diseases, such as inflammatory bowel disease, malabsorption, or radiation therapy. If the patient is immunosuppressed from AIDS, chemotherapy, or organ transplantation, or because of other medical reasons, opportunistic pathogens should be considered. Diarrhea can also be a side effect of some medications.

Physical examination

The first step in the physical examination of a patient with a diarrheal illness is to determine the patient's state of hydration. There are several signs suggestive of dehydration. For example, patients may have a sunken appearance to the eyes, dry oral membranes, or loss of skin resiliency, known as *skin tenting*. This is tested by gently pinching the skin on the back of the hand or over the sternum. In a dehydrated patient, the skin remains in a pinched or tented position. Patients may also have a decrease in blood pressure or an increase in heart rate on moving from a supine to a seated or standing position (**orthostatic changes**). If the dehydration is severe enough, the patient may have changes in mental status or dysfunction of other organ systems (e.g., kidney failure). If the patient has a fever, it may be a clue that the patient is infected with an invasive pathogen.

Examination of the abdomen may also help lead to a diagnosis. Frequently, the abdomen is diffusely tender. Examination with a stethoscope reveals that bowel sounds are present, sometimes hyperactive in quality. If the pain is localized to only one section of the abdomen, there is severe pain on palpation of the abdomen, or bowel sounds are absent, the patient should be evaluated for complications of diarrheal infection (e.g., **toxic megacolon** or intestinal perforation) or a different disease process, such as appendicitis, pancreatitis, or ovarian torsion.

Laboratory studies

Evaluation of the patient's peripheral blood cell count may reveal a leukocytosis in invasive infections. Anemia may be present in cases of severe GI blood loss or hemolytic infection. Thrombocytopenia (low platelet count) may be present in some infections. Evaluation of the patient's blood chemistry test results can show electrolyte abnormalities. Examination of the stool for red blood cells (RBCs) and evidence of inflammation (**fecal leukocytes** in the stool; Fig. 34.2) or testing for

Fig. 34.2 Gram stain of a direct fecal smear showing the presence of white blood cells, indicative of an invasive process and not an enterotoxin.

fecal lactoferrin (a neutrophil marker associated with inflammation) may help differentiate those patients who have invasive disease from those patients with toxin-mediated illnesses, viral illnesses, or parasitic infections.

Case check 34.2

A stool sample was submitted for testing. It was negative for white blood cells (WBCs) and lactoferrin, which is consistent with the history of lack of fever and blood in his stools. Combined with the clinical history (short duration of symptoms and travel history), the most likely cause is a toxin-mediated process such as that associated with enterotoxigenic *E. coli* (ETEC), the organism that causes approximately 50% of traveler's diarrhea. Viral pathogens can also cause a noninflammatory diarrhea but are less likely in this case.

Clinical presentation and pathogenic mechanisms of acute diarrhea

Based on the history, physical examination, and preliminary laboratory findings, the health care provider should be able to shorten the list of potential pathogens. The workup of the patient can then be completed in conjunction with the microbiologist to determine appropriate diagnostic methods. Several diagnostic methods exist to determine the cause of acute diarrhea. Carefully taking the history, as discussed earlier, can help formulate a differential diagnosis of expected pathogens. Another classic approach is to categorize acute diarrhea by pathogenic mechanisms. Based on certain signs and symptoms and stool sampling, diarrhea can be characterized as enterotoxin mediated or invasive. Although there may be significant overlap between these groups, this categorization is useful as an initial diagnostic approach.

Enterotoxin-mediated diarrhea

Case study

A 25-year-old female patient recently attended a picnic at a family reunion. A few hours after returning home, she experienced a sudden onset of vomiting and frequent diarrhea, with abdominal cramping. She reported not having any fever. She felt lightheaded when standing and had a rapid heart rate, 130 beats/minute (reference range 60 to 100 beats/minute). The stool was watery, without any pus or gross blood. Her symptoms resolved the next day. It was determined that several other family members who had attended the reunion developed similar symptoms.

The lack of fever and absence of blood or pus in the stool suggests an enterotoxin-mediated illness. Bacteria associated with enterotoxin production do not invade the gut wall, and the toxin does not elicit an inflammatory response. Because there is no systemic inflammatory response, patients usually do not have a fever. In the Case Study, the patient's symptomatic lightheadedness and rapid heart rate suggest significant volume depletion. Initial treatment is aimed at rehydrating the patient by administering oral or intravenous (IV) fluids.

The rapid onset of symptoms following food ingestion suggests an enterotoxin-mediated cause. In these cases, the preformed toxin is present in the ingested food. Because toxin can act proximally in the bowel (the small intestine), the incubation period is relatively short, usually less than 12 hours. When patients present to a health care provider, they usually report an illness that started the day of or the day before presentation. They typically have several (sometimes >20/day) nonbloody, watery stools and frequently have vomiting and abdominal cramping, particularly during defecation. Stool examination will be negative for RBCs and WBCs.

There are several causative organisms for **enterotoxin-mediated diarrhea**. ETEC accounts for the largest percentage of cases of diarrhea in travelers to underdeveloped areas. Other organisms responsible for enterotoxin-mediated disease include *Vibrio cholerae*, *Staphylococcus aureus*, *Clostridium perfringens*, and *Bacillus cereus*. When *S. aureus* is implicated, the source of infection can often be traced to food handlers with small, localized abscesses in the nail beds known as *paronychias*. Similar clinical syndromes are caused by other bacterial pathogens (e.g., *Plesiomonas* or *Aeromonas*) or by viruses. Noninvasive parasitic infections such as giardiasis and cryptosporidiosis or infection with *Cystoisospora belli* can also produce an afebrile diarrhea, with a negative microscopic stool examination result. However, patients with these infections typically have fewer stools per day than those with enterotoxin-mediated disease, and they usually have a more prolonged illness.

Case check 34.3

The history of food ingestion and rapid onset of symptoms in this case indicate a toxin-mediated process such as that caused by *S. aureus* or *B. cereus*. However, it is important to remember that viral and noninvasive parasitic infections such as giardiasis and cryptosporidiosis can also result in normal stool examination findings in patients with diarrhea.

Diarrhea mediated by invasion of the bowel mucosal surface

Case study

A 56-year-old male patient was being treated with clindamycin for a skin infection. After 4 days of therapy, he developed a fever and had about 15 episodes of diarrhea per day. A peripheral blood count revealed a new leukocytosis. Stool examination revealed fecal WBCs and RBCs as well as the presence of *C. difficile* toxin. The patient was treated with orally administered metronidazole, with resolution of symptoms.

The most common organisms in this category are *Salmonella enterica*, *Campylobacter* spp., *Shigella* spp., some *E. coli* strains, and *Entamoeba histolytica*. In contrast with enterotoxin-mediated diarrhea, organisms that invade the bowel mucosa cause an inflammatory response, characterized by the presence of fecal leukocytes, fever, and leukocytosis. Spread of the infection to the regional lymph nodes is unusual. However, *Salmonella* Typhi does invade the tissue spreading to the blood stream causing typhoid fever. Because the organisms

must first replicate in the colon and then invade the mucosal surface, the incubation period is usually longer than that of enterotoxin-mediated diarrhea. Because these infections involve only the superficial mucosal surface of the bowel, bacteremia or metastatic infection is infrequent. Patients may present with true dysentery syndrome, characterized by gross blood and pus in the stool. Other pathogens, such as enterohemorrhagic *E. coli*, cause bloody stools, but fever and fecal leukocytes are less common findings. *E. histolytica* has a longer incubation period than other enteric pathogens.

Case check 34.4

This patient has evidence of invasive disease based on his fever and the presence of fecal WBCs and RBCs. *C. difficile* is a common cause of invasive diarrhea after antimicrobial therapy.

Diarrhea mediated by invasion of full-bowel thickness with lymphatic spread

Case study

A 30-year-old female patient returning from South America presented to the emergency department with fever. Laboratory studies showed a mild anemia, low platelet count, and mild neutropenia. Blood cultures were sent to the laboratory. One week later, the patient developed a watery diarrhea, and stool cultures were sent to the laboratory. Stool and blood cultures were positive for *Salmonella* Typhi. The patient was treated with ciprofloxacin, with reduction of symptoms after several days.

The most common invasive enteric organisms are *Salmonella* Typhi and *Yersinia enterocolitica*. The incubation period for these infections is about 1 to 3 days. These organisms can invade the bowel wall, causing bacteremia and mesenteric lymphadenitis that can be mistaken for appendicitis. Diarrhea may be absent at the onset of the disease. RBCs and WBCs are often present in the stool. Gross blood in the stool occurs in about 25% of patients with *Y. enterocolitica* infection. Patients with *Salmonella* Typhi infection may become chronic carriers and unknowingly spread the infection to others.

Case check 34.5

This patient improved with ciprofloxacin therapy, but there is growing resistance among *S. Typhi* isolates to fluoroquinolones, especially in Asia, where azithromycin or ceftriaxone is now the recommended empiric regimen. Complications of untreated severe typhoid fever can include severe intestinal hemorrhage and intestinal perforation.

Common viral, bacterial, and parasitic pathogens

This section discusses some of the most important viral, bacterial, and parasitic causes of infectious diarrhea.

Viral pathogens

Case study

A 2-year-old male patient who attends daycare developed vomiting and diarrhea. He had a low-grade fever taken orally of 100.0°F (37.8°C), reference range 97.6°F (36.4°C) to 99.3°F (37.4°C). When the parents questioned the daycare employees, they learned that several other daycare children had similar symptoms, and several children were absent from the daycare because of illness. Examination of stool from the patient did not reveal any fecal leukocytes. The child was encouraged to drink copious fluids, and his symptoms resolved after a few days.

Viruses were suspected to be a cause of gastroenteritis from the 1940s, but no pathogen was identified in feces of sick individuals until 1972. Since then, the number of identified viral pathogens has steadily increased. Viruses pose a challenge to the microbiologist because of their small size, which precludes the use of light microscopy. Techniques used for their identification include antibody testing, antigen detection, and nucleic acid amplification of the viral genome. Due to cost and technical demands, culture in cell lines and electron microscopy are no longer used routinely.

Rotaviruses

Members of the family Reoviridae, **rotaviruses** are nonenveloped and have a 70-nm icosahedral structure. They are classified into groups, subgroups, and serotypes based on the capsid protein antigens. Rotaviruses are the most common cause of diarrhea in children younger than 5 years of age, causing an estimated 130 million episodes of diarrhea worldwide each year. Though this pathogen is primarily associated with children, it is also relevant for adults and can cause severe and protracted diarrhea in immunocompromised hosts. Rotavirus infects cells of the villi of the small intestine, leading to epithelial atrophy and proliferation of cells with secretory capacity. These changes may decrease the absorptive capacity of the bowel and increase the amount of intestinal water and electrolytes in the lumen, which results in diarrhea. Treatment is mainly supportive care. Prevention is now possible because a vaccine against rotavirus is available, and it helps reduce morbidity- and death-related diarrheal illness.

Enteric adenoviruses

Adenoviruses, members of the family Adenoviridae, are nonenveloped 70-nm viruses with icosahedral symmetry. Adenoviruses have been implicated in many illnesses, ranging from the common cold and epidemic keratoconjunctivitis (pink eye) to infectious diarrhea. It is not uncommon to have a preceding upper respiratory tract infection followed by infectious diarrhea with this agent. There are multiple serotypes, and it is postulated that associations between serotypes and syndromes can differ by geographic region. Two adenovirus serotypes, 40 and 41, are most frequently associated with infectious diarrhea. Diarrhea results from a mechanism similar to that for rotaviruses. This virus causes 1% to 8% of cases of diarrhea in the developed world.

Caliciviruses

Members of the family Caliciviridae, the caliciviruses are characterized by 32 cup-shaped depressions along the surface. Two genera are associated with GI disease in humans, *Norovirus* (formerly *Norwalk-like viruses*) and *Sapovirus* (formerly *Sapporo-like viruses*). The noroviruses are named after the original strain, Norwalk virus, which was first isolated in 1968 in patients from a town with that name in Ohio. These viruses cause an acute, self-limiting diarrheal illness associated with vomiting and low-grade fever. The disease is highly contagious and is transmitted by the fecal-oral route via contaminated food or water, by environmental fomites, or from person to person. The virus can be transmitted by the aerosolization of vomitus. Outbreaks have been reported aboard cruise ships.

Astroviruses

Members of the family Astroviridae, these viruses express different morphologies depending on the pH of the media to which they are exposed. The original characterization as a small, 28-nm virus that appears as a five- or six-pointed star is the morphology at alkaline pH; the virus has a 41-nm icosahedral appearance with defined spikes at other pH values. The mechanism of the diarrhea resulting from these viruses is not well understood, but animal studies suggest that an osmotic diarrhea may develop from inflammatory infiltrates in the lamina propria and the intestinal villus atrophy. These agents usually cause infection in older adults or the very young.

Coronaviruses

Diarrhea may be present as systemic manifestations of other viral infections. Notably, severe acute respiratory syndrome–coronavirus-2 (SARS-CoV-2) and its clinical disease, Coronavirus Disease 2019 (COVID-19), may present initially with malaise and diarrhea. Though this condition is primarily respiratory, atypical presentations can occur with GI manifestations as main symptoms. This can occur with other viral respiratory illnesses as well. Understanding the local prevalence of SARS-CoV-2 in a community and assessing whether the patient has sick contacts may help increase suspicion for COVID-19. Other members of the family Coronaviridae have also been associated with gastroenteritis.

Case check 34.6

Viruses such as the rotavirus, adenovirus, and norovirus usually cause a self-limiting, noninflammatory diarrhea. Treatment is supportive.

Bacterial pathogens

Case study

A 30-year-old male patient hosted a barbecue for a football weekend at which he served chicken. On the Tuesday after the event, the patient and several other people who had attended the barbecue developed fever and diarrhea. Stool studies from the patient revealed RBCs, WBCs, and numerous curved, gram-negative rods. After several days, the patient and other attendees recovered without complications.

Bacteria are a common cause of infectious diarrhea. Several agents are known to cause diarrhea by various mechanisms, ranging from toxin production (performed in food or produced in the intestine) to mucosal invasion. Antimicrobial agents are used for the treatment of some of these illnesses. The clinical microbiologist has an important role in identifying these organisms.

Campylobacter jejuni

Campylobacter jejuni is the most common bacterial cause of gastroenteritis in the world. For most cases, antimicrobial therapy is not necessary. Because of the widespread misuse of antimicrobial agents, these organisms are developing significant resistance to agents commonly used to treat diarrheal illnesses (e.g., fluoroquinolones). Guillain-Barré syndrome, a life-threatening neurologic disease, and reactive arthritis are complications of infection by *C. jejuni*.

Infection with this organism usually results in a self-limiting disease characterized by fever, abdominal cramping, and diarrhea. The incubation period is 2 to 5 days, but in some cases extends up to 10 days. Diarrhea is often preceded by a period of fever, malaise, myalgias, and abdominal pain. Stools may have gross blood and pus present. The diarrhea usually lasts 2 to 3 days, but abdominal discomfort may persist for several days after resolution of the diarrhea. The pathogen can be cultured from stool for several weeks after the illness has subsided. The environmental reservoirs of *Campylobacter* are wild and domestic animals, typically birds.

Contaminated poultry is often the source of the infection. Other outbreaks have been traced to contaminated meat, water, and unpasteurized milk. Although there is prolonged fecal shedding of the organism, there is little person-to-person transmission of the infection. If antimicrobials will be used to treat the infection (in the case of immunocompromised patients or those with severe or prolonged illness), a macrolide antibiotic is preferred because of the increasing rates of fluoroquinolone resistance. Because the organism is heat sensitive, thorough cooking of meat and poultry is effective in preventing human infection. Although food irradiation may be effective in decreasing the amount of bacteria present in uncooked food, this technique is feared by the public. *Campylobacter coli* is also a relatively common cause of gastrointestinal tract infections and produces signs and symptoms similar to *C. jejuni*.

Salmonella species

Gastroenteritis and food poisoning

Nontyphoidal *Salmonella* spp. can lead to gastroenteritis through the ingestion of contaminated meat, poultry, eggs, dairy products, and aquaculture-farmed fish and shellfish. A wide variety of nontyphoidal *Salmonella* serotypes are present in animal hosts, most notably birds and reptiles.

Symptoms usually start between 6 and 48 hours after ingestion of contaminated foods and consist of nausea, vomiting, and diarrhea. Patients may also develop fever, headaches, and myalgias. The illness is usually self-limiting and resolves within a few days. Antimicrobials are not recommended in most cases because they do not shorten the course of the illness and can promote long-term carriage.

Enteric fever

Salmonella Typhi causes the most severe form of **enteric fever**, typhoid fever. Unlike the other serotypes of *Salmonella*,

humans are the only known host for this pathogen. The infection is commonly spread through fecally contaminated food or water. In the United States, there are approximately 350 cases per year. Mortality can be as high as 15%.

In the initial stages of the infection, the pathogen invades the small and large bowel walls, creating an inflammatory response. The bacteria survive inside host cells and are therefore termed *intracellular pathogens*. The infection spreads throughout the body via the regional lymph nodes and bloodstream. The initial symptoms of infection are headache, fever, general malaise, and abdominal tenderness. Once the organism has spread throughout the body, it reaches the gallbladder and Peyer patches in the colon, initiating the diarrheal stage of the illness. The organism can frequently be recovered from blood and later stool cultures. Immunocompromised hosts and patients with HIV have a higher risk of invasive *Salmonella* disease and bacteremia. The incidence of salmonellosis in HIV-positive patients has been estimated to be as high as 20 to 100 times greater than that in an immunocompetent host. Thus an HIV test should be considered for patients with *Salmonella* bacteremia. *Salmonella enterica* serotype Enteritidis and *Salmonella enterica* serotype Typhimurium are the two most important serotypes of *Salmonella* transmitted from animals to humans in most parts of the world. These agents typically produce a gastroenteritis without bacteremia.

Appropriate antimicrobial use results in clinical improvement; however, stool cultures often remain positive, which can serve as a source of infection for other individuals. Some patients can develop chronic colonization of their gallbladder and biliary tree, leading to persistent shedding of the organism, with potential transmission to others (the classic Typhoid Mary case).

Shigella species

Very closely related to *Escherichia* spp., *Shigella* spp. are responsible for a diarrheal illness characterized by gross blood and pus in the stool. There are four recognized *Shigella* spp.: *S. sonnei* (the most common in the United States), *S. flexneri*, *S. dysenteriae*, and *S. boydii*. Because the ID₅₀ of this organism is very low (possibly <100 organisms), it is among the most easily communicable bacterial diarrheal pathogens. Invasion into the intestinal mucosa leads to ulceration and a marked inflammatory response; the organism usually does not invade past the mucosa or spread into the bloodstream. The bacteria produce several toxins, including the Shiga toxin, which can have cytotoxic, enterotoxic, and neurotoxic effects. In 2016, there were 12,597 cases of shigellosis, in the United States. Children 1 to 4 years old had the highest incidence of all age groups. Multiple outbreaks have occurred in recent years, including outbreaks in people experiencing homelessness in the Pacific Northwest in 2021 and other major metropolitan areas.

The incubation period of the disease can range from 1 to 7 days, but most patients develop symptoms within 12 to 50 hours after exposure. The initial symptoms are fever, malaise, fatigue, and anorexia. A watery diarrhea with abdominal cramping and tenesmus then develops, which may progress to the patient having gross blood and pus in the stool. Although the disease is often self-limiting, antimicrobial treatment is recommended as multiple randomized controlled trials have consistently shown clinical benefit with antimicrobial use. Resistance is on the rise and can vary, with rising trimethoprim/sulfamethoxazole resistance. Quinolones are favored when susceptibility is unknown.

Table 34.4 Diarrheagenic *Escherichia coli*

Group	Major virulence factors	Reported food sources
ETEC	Adhesins LT and ST toxins	Fresh fruits and vegetables, scallops, tuna paste, soft cheeses
EIEC	Invasion proteins	Cheese, guacamole
EHEC	Intimin (adherence to intestinal mucosa)*Shiga toxins	Undercooked beef, sausage, chicken, lunch meats, deer jerky, lettuce, radishes, alfalfa sprouts, potatoes, milk, apple juice, cider, cheese curds
EPEC	Intimin (adherence to intestinal mucosa) Type IV bundle-forming pili Surface-associated filaments Translocated intimin receptor ^a	Fresh fruits and vegetables, likely infant formula
EAEC	Aggregative adherence fimbriae Dispersin Plasmid-encoded toxin	Likely foodborne, possibly fruits and vegetables, other food sources uncertain
DAEC	Adhesins	Likely contaminated food or water and also through person-to-person contact

DAEC, Diffusely adherent *E. coli*; EAEC, enteroaggregative *E. coli*; EHEC, enterohemorrhagic *E. coli*; EIEC, enteroinvasive *E. coli*; EPEC, enteropathogenic *E. coli*; ETEC, enterotoxigenic *E. coli*; LT, heat labile; ST, heat stable.

^aIntimin and translocated intimin receptor are encoded by the locus of enterocyte effacement.

Escherichia coli

Although this species is a normal inhabitant of the human GI tract, six different strains of *E. coli* have been associated with disease (Table 34.4). *E. coli* O157 illnesses are most often linked to vegetable row crops (such as leafy greens) and beef.

Enterotoxigenic *Escherichia coli*

Enterotoxigenic *E. coli* (ETEC) produces adhesins that bind to intestinal mucosa and enterotoxins, which are heat stable enterotoxin (ST) or heat labile enterotoxin (LT) and are responsible for diarrhea. LT is similar to *V. cholerae* toxin. ST binds to guanylate cyclase, leading to increased intracellular cyclic guanosine monophosphate (cGMP) levels and active efflux of water and electrolytes from the intestinal cells. Clinically, patients have a watery diarrhea that lacks RBCs and WBCs. This is a common cause of traveler's diarrhea.

Enteroinvasive *Escherichia coli*

Enteroinvasive *E. coli* (EIEC) produces an infection similar to *Shigella* infection. Patients usually develop a watery diarrhea similar to that produced by ETEC. Some patients then progress to an invasive-type diarrheal syndrome, with fever, abdominal cramping, and bloody stools. Fecal leukocytes are abundant.

Enterohemorrhagic *Escherichia coli*

Enterohemorrhagic *E. coli* (EHEC) strains produce Shiga toxin 1 and/or Shiga toxin 2 and possess the locus of enterocyte

effacement that mediates attachment to enterocyte membrane and destruction of the brush border microvilli. Infection usually starts as a watery diarrhea. However, over the next 1 or 2 days, abdominal pain increases, and stools become bloody. Stool may contain some leukocytes, so there may be some confusion between this infection and EIEC infection or shigellosis. Although the disease is usually self-limiting, patients can develop hemolytic-uremic syndrome (HUS), characterized by hemolytic anemia, low platelet count, and kidney failure. The *E. coli* strain O157:H7 is among the principal causes of this syndrome. It is uncertain whether antimicrobial therapy decreases the probability of developing HUS. There is some concern that subtherapeutic antibiotic dosing may actually increase the risk of developing the disease by stimulating bacterial toxin production.

Enteropathogenic *Escherichia coli*

Enteropathogenic *E. coli* (EPEC), enteroaggregative *E. coli* (EAEC), and diffusely adherent *E. coli* (DAEC) are collectively referred to as *enteroadherent E. coli* in some classification schemes. Although the mechanism of diarrhea is not completely understood, it seems that the organisms express various factors that facilitate their adherence to intestinal cells. This causes disruption and destruction of the brush border of the cells and other intestinal cell derangements, reducing the absorptive capacity of the cells and leading to electrolyte abnormalities and diarrhea. These organisms commonly affect children in nurseries and daycare centers. Patients often have low-grade fever, vomiting, and diarrhea.

Enteroaggregative *Escherichia coli*

EAEC also adheres to the intestinal surface but in a more clumped or aggregative fashion. These organisms apparently first adhere to the intestinal wall via various adhesive molecules, cause an increase in the production of mucus, and then induce an inflammatory response by host cytokine release. EAEC is being increasingly recognized as a cause of traveler's diarrhea. Infections with these organisms can range from asymptomatic to a chronic watery diarrhea.

Diffusely adherent *Escherichia coli*

DAEC is characterized by a diffuse adherence pattern on cultured HeLa or HEP-2 cells. These strains express unique adhesion molecules first described in urinary pathogenesis. Later it was shown that these strains were responsible for diarrhea in children 18 months to 5 years of age, but not in adults. In fact, these strains can be part of the asymptomatic intestinal microbiota in older children and adults. Clinical studies have not demonstrated characteristic signs and symptoms in children infected with DAEC. Although a large percentage of children present with diarrhea, abdominal pain, and vomiting, the frequencies of these complaints are not different from those of children infected with EPEC, EAEC, or ETEC.

Vibrio species

Vibrio species are curved, gram-negative rods, similar in appearance to *Campylobacter*. They are usually found in water environments and can contaminate fish and shellfish. Although many species of *Vibrio* are implicated in human disease, one of the best known is *V. cholerae*, the causative agent of **cholera**. This organism creates a well-studied enterotoxin that consists of two subunits (a core A subunit surrounded

by five B subunits). The B subunits permit attachment to the small bowel mucosa; the A subunit then enters the cell. Once in the cell, through various enzymatic effects, the toxin results in an increase in cyclic adenosine monophosphate (cAMP), which causes the cell to secrete large amounts of water and electrolytes. This increased secretion causes the rice water stools characteristic of cholera. Many liters of stool can be produced daily, and patients without adequate medical care are at risk of death from dehydration. Although the quantity of diarrhea can be impressive, it is toxin mediated and noninflammatory, so the stools are free from RBCs and WBCs.

There are many serogroups (serovars) of *V. cholerae*. Serogroups O1 and O139 have been implicated as causes of epidemic cholera. The other serogroups can also cause illness but have not been associated with the epidemic form of the disease. Two other *Vibrio* spp. that can cause GI illness are *Vibrio parahaemolyticus* and *Vibrio vulnificus*, although other species have been implicated as well. Without treatment, case fatality rates can be as high as 50%.

Vibrio parahaemolyticus is the most common *Vibrio* species responsible for disease in the United States and is fairly common worldwide. Patients with this infection, unlike those with classic cholera, can have fever and evidence of fecal inflammation, suggesting that there is some potential for mucosal invasion. *V. vulnificus* is the most virulent of all non-cholera vibrios, causing a fulminant illness characterized by sepsis and bullous skin lesions in patients with a recent ingestion of shellfish (e.g., raw oysters). This *Vibrio* species is part of the marine microbiota, making it a common colonizer of a large percentage of oysters harvested in the warmer months. Compromised patients, particularly those with liver disease, are more susceptible to the development of fulminant disease.

Yersinia enterocolitica

Related to the organism responsible for bubonic plague, *Yersinia enterocolitica*, a gram-negative bacillus, can produce gastroenteritis. Infections with this organism, which are more common in the winter months, have been linked to meat, unpasteurized milk, other dairy products, and chitterlings. Refrigeration does not prevent growth of this organism.

Patients can present with a self-limiting enteritis consisting of fever, nausea, diarrhea, and abdominal pain or can develop a more invasive disease, with spread of the organism to the mesenteric lymph nodes. This mesenteric lymphadenitis can be mistaken for appendicitis. Stool studies will show both RBCs and WBCs. Because the organism has the ability to invade and spread throughout the body, distant foci of infection and abscesses can also develop.

Clostridioides difficile

First identified in 1935 as an anaerobic, gram-positive, spore- and toxin-producing organism, *C. difficile* was later found to be a causative agent of antibiotic-associated diarrhea. *C. difficile*-associated disease (CDAD) was initially reported in patients receiving clindamycin; however, almost all classes of antimicrobials have been linked to this infection. The initial event in the pathogenesis of the disease is the antimicrobial-induced disruption of the indigenous bacterial biota of the colon that allows the overgrowth of *C. difficile*. The organism produces two different exotoxins, toxins A and B, which bind to surface epithelial cell receptors, leading to inflammation, mucosal injury, and

diarrhea. The development of characteristic pseudomembranes in the colonic mucosa, composed of neutrophils, fibrin, mucin, and cellular debris, is pathognomonic of CDAD. In mild cases, these pseudomembranes are absent.

Other important risk factors for asymptomatic colonization and infection with this bacterium include a recent hospitalization and residence in a long-term care facility. Cases of community-acquired disease, unrelated to antimicrobial use, have been described. The organism is transmitted from person to person via the fecal-oral route and can easily be passed from a colonized patient to other patients in the hospital by health care personnel who do not observe proper hand hygiene. *C. difficile* has been cultured from inanimate hospital surfaces.

The clinical presentation of CDAD ranges from a mild watery diarrhea to a life-threatening toxic megacolon, which requires surgical intervention. Patients with severe disease often present with abdominal pain, leukocytosis, and fever in addition to diarrhea. An epidemic and more virulent strain of *C. difficile* has been identified. This epidemic strain, referred to as BI/NAP1/027, has increased virulence that is attributed to the overexpression of toxin-encoding genes producing larger amounts of toxins, which causes a more aggressive form of the disease compared with the nonepidemic strains.

Diagnosis of CDAD is often made on clinical grounds or by detecting the presence of *C. difficile* toxins in a stool sample. The finding of pseudomembranes during rectosigmoidoscopy is highly suggestive of the disease. Orally administered metronidazole or vancomycin remains the mainstay treatment. Vancomycin has been shown to be superior to metronidazole. Recent studies have shown better performance by fidaxomicin, and it is now the recommended first-line agent. However, vancomycin remains an acceptable first choice when fidaxomicin is not available.

Listeria monocytogenes

A gram-positive, non-spore-forming facultative anaerobic bacillus, *L. monocytogenes* is best known for causing systemic disease, such as meningitis. However, several outbreaks of gastroenteritis have implicated this intracellular pathogen. The presence of this organism in an asymptomatic individual is not necessarily a cause for concern because 5% to 10% of healthy adults transiently carry *L. monocytogenes* in the bowel at any given time. Most outbreaks have been linked to contaminated deli meats and cheeses. In 2021, frozen, fully cooked chicken products, such as chicken strips and diced chicken, and products made with fully cooked chicken were associated with *L. monocytogenes* contamination causing several illnesses, hospitalizations, and deaths.

Helicobacter species

Although *H. pylori* (Fig. 34.3) does not cause diarrhea, it has been associated with peptic ulcer disease and gastric carcinoma. Infection with *H. pylori* is common. Active infection can be diagnosed by detecting the organism on a gastric biopsy specimen or through a urea breath test (Fig. 34.4). This testing is based on the organism's high urease activity. ¹³C- or ¹⁴C-labeled urea will, when ingested, produce labeled CO₂ in the patient's breath if the organism is present. Other *Helicobacter* spp. (e.g., *H. cinaedi*, *H. fennelliae*) are presumed to play a role in diarrheal illnesses.

Fig. 34.3 **A**, Microscopic morphology of *Helicobacter pylori* Gram stained from a colony. **B**, Gray translucent *H. pylori* colonies grown on charcoal cefoperazone deoxycholate agar culture medium. **C**, Gram stain on gastric mucus. (Courtesy American College of Gastroenterology and DiaSorin, Stillwater, MN.)

Other bacterial pathogens

Aeromonas spp. and *Plesiomonas shigelloides* have been associated with a watery diarrhea. *Edwardsiella tarda*, associated with fish and shellfish, is a rare cause of gastroenteritis. Organisms responsible for sexually transmitted infections can also cause GI disease. *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Treponema pallidum* subsp. *pallidum*, and herpes simplex virus may all cause a proctitis with loose stools and pain on defecation, usually in patients infected through receptive anal intercourse.

Case check 34.7

Campylos is Greek for "curved," and *bacter* means "rod," thus giving this common curved, gram-negative rod frequently seen on direct Gram-stained smear of stool its name. Other causes of bacterial diarrhea include *Salmonella* spp., *Shigella* spp., *E. coli*, *Vibrio* spp., *Y. enterocolitica*, *C. difficile*, and *L. monocytogenes*.

Parasitic pathogens

Case study

A 21-year-old male patient recently spent 2 weeks backpacking through the Appalachian mountains. One week after his return, he developed cramping abdominal pain, increased flatulence, and diarrhea. Otherwise, he felt well and had no other symptoms. Stool examination did not reveal any RBCs or WBCs, but did show cysts consistent with *G. duodenalis*, and antigen detection confirmed the diagnosis. He was successfully treated with metronidazole.

Fig. 34.4 The urea breath test. (Courtesy American College of Gastroenterology and DiaSorin, Stillwater, MN.)

Parasitic infections account for a small percentage of diarrheal illnesses in the United States. They frequently have a longer incubation period than bacterial and viral infections and have a longer clinical course. The diagnosis is based on microscopic examination of the stool or by antigen detection and multiplex nucleic acid methods for some of the parasites.

Giardia duodenalis

Probably the most commonly identified intestinal parasite in the United States, *G. duodenalis*, is usually acquired by ingestion of contaminated water or via person-to-person spread. Because the organism is found in mountain streams, campers and others who engage in outdoor activities are at risk of

infection if they drink contaminated water. After an incubation period of 1 to 2 weeks, patients develop nausea, vomiting, flatulence, cramping, and diarrhea. Because the organism is not invasive, patients typically do not have fever or fecal leukocytes on examination. Stool examination reveals a characteristic trophozoite and/or cyst. The yield of finding the parasite is higher if duodenal aspirates are obtained through endoscopy or the string test (a capsule contains a string that is swallowed and later retrieved by pulling through the oral cavity). Antigen detection and nucleic acid amplification tests are available.

Entamoeba histolytica

Amebiasis from *E. histolytica* (Fig. 34.5) can cause GI and disseminated disease. Because of the invasive nature of *E. histolytica*, the clinical presentation is characterized by fever and bloody diarrhea. However, the range of illness is broad, and infected patients may present with only mild, watery diarrhea, which complicates the diagnosis. Trophozoites and cysts may be identified in the stool. Antigen detection, nucleic acid amplification, and serologic tests for diagnosis are also available. The organism is morphologically similar to the nonpathogenic *Entamoeba dispar*, *Entamoeba moshkovskii*, and *Entamoeba bangladeshi*, also found in the intestinal tract, which has led to much confusion when estimating the true frequency of the disease. The trophozoites of *E. histolytica* can migrate to the liver and cause a liver abscess.

Cryptosporidium parvum and Cryptosporidium hominis

In otherwise healthy individuals, *Cryptosporidium parvum* and *C. hominis* cause an illness characterized by abdominal cramping, watery diarrhea, vomiting, fever, headache, and anorexia. Symptoms generally last about 10 days but may recur after initial abatement. Significant differences exist in clinical manifestations among different *Cryptosporidium* spp. and *C. hominis* subtypes in pediatric cryptosporidiosis.

This organism is resistant to chlorine, so public swimming pools can be the source of an outbreak. In fact, during the summer of 2007, Utah experienced a statewide outbreak of *Cryptosporidium* infection linked to recreational water venues. Approximately 5700 cases were identified. Other sources of exposure include fecally contaminated food or water, international produce, and person-to-person spread. Several

Fig. 34.5 *Entamoeba histolytica* trophozoites (trichrome-stained smear).

outbreaks have been associated with potable water in developing countries. In developing countries, the most common presentation is diarrhea in children. These organisms are acid fast; therefore they can be detected in stool specimens with this staining technique. However, today, they are generally detected by antigen detection or polymerase chain reaction-based assays.

Cyclospora cayetanensis and Cystoisospora belli

Cyclospora cayetanensis has been associated with outbreaks of diarrhea from contaminated water, food, and produce. Illness in the immunocompetent patient generally consists of an acute onset of watery diarrhea, which usually lasts for about 10 days. Patients also may have a prodromal syndrome of myalgias and arthralgias; other symptoms include cramping, fever, profound fatigue, nausea, and vomiting. In healthy individuals, diarrheal disease from *Cystoisospora belli* (formerly *Isospora belli*) is similar to other parasitic infections. Most cases are self-limiting and consist of watery diarrhea and abdominal cramps. In the United States, most cases are seen in travelers returning from endemic areas. Antigen detection assays are not commercially available and serologic tests have minimal value. Some in-house nucleic acid amplification tests have been described. Diagnosis relies on detection of oocysts in unstained or modified acid fast–stained stool samples.

Microsporidia

The fungi *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* are members of the order Microsporidia. These pathogens can cause illness similar to that caused by *C. parvum* and *C. cayetanensis*. Disease ranges from an asymptomatic to self-limiting diarrhea in healthy individuals. This organism is an important cause of diarrhea in immunocompromised individuals, particularly in patients with AIDS. Special staining of stool specimens is required to observe these organisms under light microscopy; their small size, 1.5 to 4.0 μm , makes detection difficult. Occasionally, they will stain acid fast.

Case check 34.8

Suspect a parasitic cause of infection if the patient has an epidemiologic history of foreign travel or activities such as hiking and a clinical picture consistent with a mild, chronic diarrhea. Parasites can cause severe disease in immunocompromised patients. Diagnosis is often made by direct examination of the stool with special stains, such as acid-fast stains, and antigen testing.

Other parasitic infections

In addition to the protozoal parasitic infections mentioned earlier, there are many other organisms that can cause human disease, most of which are rare in the United States. Some of these organisms include *Ascaris lumbricoides* (common roundworm), *Strongyloides stercoralis*, *Ancylostoma* and *Necator* spp. (hookworms), *Trichuris trichiura* (whipworm), and *Enterobius vermicularis* (pinworm). Others include *Capillaria philippinensis*, which is usually found in Thailand, Iran, Egypt, and the Philippines, and *Trichinella spiralis*, which is acquired by eating poorly cooked pork. *Anisakis* infection is associated with

eating contaminated sushi or sashimi. The parasitic organisms listed here are a sample of the human parasites. Refer to [Chapter 28](#) for a more detailed discussion.

Diarrhea in special circumstances

Toxic agents of food poisoning

Case study

A 32-year-old female patient ate a fish dinner at a restaurant. Before she returned home from the restaurant, she began to feel warm. She developed headache and abdominal cramping with some diarrhea and was generally flushed. Symptoms continued for a few hours and then abated.

A foodborne outbreak is defined as the occurrence of GI or neurologic symptoms within 72 hours of ingesting a contaminated meal. The most commonly identified bacterial agents involved in foodborne outbreaks are *Salmonella* spp., *C. jejuni*, *S. aureus*, *Clostridium botulinum*, and *C. perfringens*. *G. duodenalis*, *Cryptosporidium*, and *Cyclospora* have also been associated with outbreaks, usually linked to contaminated fruits and vegetables.

Chemical intoxications are often associated with fish consumption. The case above is the typical presentation of **scombroid**. This syndrome, which consists of flushing, headache, and crampy abdominal pain with diarrhea, is caused by ingesting contaminated fish (often tuna, mackerel, or yellow jack). The tissues of the fish contain histamine and enzyme inhibitors, which are responsible for the symptoms. The symptoms usually start within 1 hour of ingestion and usually last only several hours.

Ciguatera is caused by a toxin, ciguatoxin, produced by dinoflagellates. This toxin accumulates in fish as it passes up the food chain. Most cases are associated with eating snapper, sea bass, grouper, or barracuda. The symptoms include diarrhea, abdominal pain, weakness, paresthesias, and headache. Symptoms often begin within 1 to 2 hours of eating the contaminated fish and may progress to respiratory failure and hypotension. Because an antitoxin is not available, patients are treated supportively.

Paralytic shellfish poisoning is associated with eating contaminated clams, mussels, and scallops. Usually occurring during the summer months, paralytic shellfish poisoning produces a syndrome similar to ciguatera. One of the deadliest toxins, tetrodotoxin, which can be found in the puffer fish, causes death in more than 50% of patients exposed. The contaminated food appears normal in each of these cases of toxin-mediated food poisoning. Prevention is aimed at locating and removing sources of contaminated fish. [Table 34.5](#) outlines several of the most common foodborne pathogens.

Returning travelers

Traveler's diarrhea is a common problem in patients visiting developing countries. Although most cases are often mild and self-limiting, it can lead to significant morbidity and disrupt the traveler's itinerary. Traveler's diarrhea usually

occurs within the first 2 weeks of travel. Other symptoms include malaise, abdominal pain, fever, nausea and vomiting, and occasionally blood in the stool. The CDC has classified the risk of developing the disease by geography, as shown in [Fig. 34.6](#). The destinations holding the highest risk for traveler's diarrhea include Asia, Africa (excluding South Africa), Central America, and Mexico.

The infectious causes of traveler's diarrhea are multiple, including many of the bacterial, viral, and parasitic organisms already described. The most common cause of traveler's diarrhea is ETEC, which causes approximately 50% of cases. Other causes include EAEC, *Salmonella*, *C. jejuni*, and *Shigella* spp. Rotaviruses are the most common viral GI pathogen. Parasitic infections are less commonly associated with typical traveler's diarrhea. However, travelers to certain areas are at a higher risk for such infections; for example, travelers to mountainous regions, especially if they are camping and drinking spring water, are at increased risk for *G. duodenalis* infection. The two geographic areas with the highest rates of *Giardia* infection are Nepal and St. Petersburg in Russia. For up-to-date information regarding management of traveler's diarrhea, refer to the CDC website. Currently, prophylaxis is not recommended universally; however, for individuals in whom diarrhea may have severe consequences, bismuth subsalicylate (Pepto-Bismol), two tablets twice daily, has been proven to decrease the frequency of traveler's diarrhea. Travelers are often provided with a 5-day course of azithromycin for self-treatment. Fluoroquinolones are no longer recommended empirically because of growing resistance among bacterial GI pathogens.

Immunocompromised hosts

Modern medicine has increased the number of people who are immunocompromised because better treatments for chronic diseases are available. Failing organs can now be replaced, and those who have congenital immunodeficiency are living longer. Immunocompromised hosts include individuals with AIDS; cancer patients, especially while receiving chemotherapy; those who have received a solid organ or bone marrow transplant; and those with chronic diseases such as rheumatoid arthritis that require continuous immunosuppression.

All of the pathogens described earlier can cause diarrhea in the immunocompromised host. Usually, the clinical course is more severe and of longer duration. These patients are also at risk for developing infections with opportunistic organisms. **Opportunistic pathogens** generally do not cause disease in healthy individuals, but they cause significant disease in susceptible hosts. In addition to infectious diarrhea, immunocompromised patients may also develop diarrhea caused by drugs, graft-versus-host disease, or the disease process itself, such as in HIV enteropathy.

Mycobacterial disease, which typically causes pulmonary disease, can spread and cause infection of the GI tract in immunocompromised individuals. The two most common mycobacteria causing disease in these hosts are *Mycobacterium tuberculosis* and *Mycobacterium avium* complex. In HIV-infected patients, *Mycobacterium avium* complex is rarely seen unless the CD4 cell count drops below 50/ μ L. Patients may present with abdominal pain and diarrhea, which sometimes turns bloody. Other symptoms such as weight loss, fevers, and night sweats are often present.

Table 34.5 Compendium of common foodborne diseases

Average incubation period	Organism	Average duration	Implicated foods	Typical symptoms	Comments
2–16 hours	<i>Bacillus cereus</i>	1 day	Boiled and fried rice, meats, vegetables	Nausea, vomiting, (emetic) abdominal cramping, watery diarrhea	Produces two toxins: one emetic form that causes nausea and vomiting within hours, and one diarrheic form; common year-round; isolation of large numbers of bacteria from implicated foods and patient stool
6–72 hours	<i>Vibrio parahaemolyticus</i>	3 days	Shellfish	Abdominal pain, vomiting, fever, watery diarrhea	Blood sometimes in stool; common in spring, summer, and fall in coastal states; stool culture using TCBS medium recommended
6–72 hours	<i>Vibrio cholerae</i>	3–7 days	Seafood, water	Rice water stools, severe diarrhea, no fever	No blood or mucus in stool; mechanism of action, in vivo enterotoxin production; no tissue invasion; stool culture using TCBS medium recommended
<8 hours	<i>Staphylococcus aureus</i>	<1 day	Egg salad, meat, poultry, pastries	Abrupt onset of nausea, abdominal pain and projectile vomiting, infrequent diarrhea, no fever	Mode of infection is ingesting preformed enterotoxin in foods; common in summer; ELISA or reverse passive latex agglutination enterotoxin test
8–22 hours	<i>Clostridium perfringens</i>	1 day	Beef, poultry, gravy, fish	Abdominal cramping, watery diarrhea; vomiting and fever uncommon	In vivo enterotoxin production; unlike <i>Staphylococcus aureus</i> , viable organisms must be ingested for disease to occur; common in fall, winter, and spring
12–48 hours	<i>Salmonella</i> sp.	3 days	Eggs, dairy products, fowl, beef	Fever, abdominal cramping, diarrhea, mild vomiting	WBCs in stool; common in summer; culture and serologic identification
16–48 hours	<i>Yersinia enterocolitica</i>	1 day to 4 weeks	Milk, pork	Fever, severe abdominal pain, diarrhea	WBCs and RBCs in stool; common in winter
18–36 hours	<i>Clostridium botulinum</i>	Weeks to months	Vegetables, fruits (canned foods), fish, honey (infants)	Nausea, vomiting, diarrhea, paralysis	Mode of infection is ingesting preformed neurotoxin; common in summer and fall
24–72 hours	<i>Shigella</i> spp.	3 days	Egg and tuna salads, lettuce, milk	Fever, abdominal cramping, diarrhea, occasional vomiting	WBCs, RBCs, and mucus in stool; tissue invasion common mechanism of action; common in summer; culture and serologic identification
24–72 hours	Enterotoxigenic <i>Escherichia coli</i>	3 days	Fruits, meats, pastries, salads	Abdominal cramping, watery diarrhea, no vomiting or fever	In vivo enterotoxin; major cause of traveler's diarrhea; year-round distribution; patient history includes travel to Mexico and other developing countries
24–72 hours	Enterohemorrhagic <i>E. coli</i>	3 days	Undercooked ground beef, apple cider	Watery diarrhea progressing to bloody diarrhea, abdominal cramping, no fever or vomiting	Implicated Shiga-toxin producing <i>E. coli</i> ; organisms disappear rapidly from stool; culture of sorbitol-negative <i>E. coli</i> from stool using SMAC plate recommended

ELISA, Enzyme-linked immunosorbent assay; RBCs, red blood cells; SMAC, sorbitol MacConkey; TCBS, thiosulfate–citrate–bile salts–sucrose; WBCs, white blood cells.

Diagnosis is often made based on positive blood cultures in disseminated disease.

Cytomegalovirus (CMV) is an opportunistic virus that can lead to diarrhea. CMV can infect many organs, including the retina, lungs, and GI tract. It can cause esophageal ulcers, leading to painful swallowing, and colitis. Typical

symptoms consist of watery diarrhea, abdominal pain, and blood in the stool. Fever is often present. The diagnosis is established with colonoscopy; findings include patchy erythema, edema, erosions, and ulcerations. Intracytoplasmic inclusion bodies are seen on microscopic evaluation of tissue biopsy samples.

Fig. 34.6 Geographic distribution of risk for traveler's diarrhea.

GI histoplasmosis should be considered in HIV-infected patients living in endemic regions who present with fever, abdominal pain, weight loss, diarrhea, GI obstruction, abdominal mass, hepatosplenomegaly, or intestinal perforation. Diagnosis is made by stool culture for fungi, urine *Histoplasma* antigen testing, or pathologic examination of GI tissue specimens.

Before the introduction of highly active antiretroviral therapy (HAART), *Cryptosporidium* spp. caused diarrhea as the presenting illness in up to 50% of HIV-infected patients. Morbidity is now drastically decreased in the era of HAART, but *Cryptosporidium* spp. are still a problem in countries with limited access to HAART. Diagnosis is made by detecting oocytes with modified acid-fast stain of the stool or a direct fluorescent antibody testing. Modified acid-fast stains also detect *Cyclospora*, *Cystoisospora*, and microsporidia.

Strongyloidiasis is a parasitic infection caused by the intestinal nematode *Strongyloides stercoralis* and is endemic in tropical and subtropical regions of the world. Most patients are asymptomatic, but immunocompromised patients may develop hyperinfection syndrome caused by an increased number of larvae. Hyperinfection syndrome may present with dyspnea, pleuritic pain, and hemoptysis as the larvae migrate to the lungs, penetrate the alveoli, ascend the tracheo-bronchial tree, and are then swallowed. Diagnosis is made by stool testing for ova and parasites, complete blood count to check for eosinophilia, and serologic testing.

The pathogens discussed are only a few of the many organisms that cause disease in immunocompromised hosts. Thus the diagnostic workup in these patients is often more extensive. Guided by the history and epidemiologic clues, such as recent travel, diagnostic testing usually includes stool cultures for

bacterial and fungal organisms, ova and parasite stool examinations, antigen detection or nucleic acid amplification for certain parasites and viruses, special staining, and serologic testing for particular organisms. Endoscopy is often done in severe or recurrent disease for a definitive diagnosis. If infectious causes are ruled out, noninfectious causes should be investigated.

Laboratory diagnosis of gastrointestinal pathogens

Specimen collection and handling

Stool specimens should be transported to the laboratory shortly after collection, avoiding refrigeration if possible. Preservatives must be avoided if bacterial cultures are ordered. However, if the stool is to be examined for ova and parasites, it should be transported in media containing preservatives such as polyvinyl alcohol or formalin. If rectal swabs for bacterial culture are to be processed, Cary-Blair or a similar transport medium should be used. Due to high sensitivity and specificity and rapid turnaround time, multiplex polymerase chain reaction has replaced routine culture in many large microbiology laboratories.

Direct microscopic examination

Microscopic examination of the stool may reveal WBCs in cases of inflammatory diarrhea (e.g. *Salmonella*, *Shigella*, *Yersinia*, *Campylobacter*, EIEC, and various *Vibrio* spp.).

RBCs may be present because of intestinal wall bleeding. The bacteria may be visible on direct microscopic examination of the stool. The presence of gram-negative, curved rods with a “seagull wing” appearance (Fig. 34.7) suggests *Campylobacter* or *Vibrio* infection. If wet mount or hanging drop preparations are performed in a patient with *C. jejuni* infection, characteristic darting motility may be seen. *E. histolytica* may also be seen on direct examination in patients with bloody diarrhea.

Culture

Selective and differential culture media are commonly used to attempt to identify bacterial pathogens in stool. Selective media contain antimicrobials or chemicals that limit the growth of normal bacterial biota and enhance the growth of pathogenic bacteria. The differential aspect of the medium often allows differentiation of bacterial species based on colony morphology; the differences in colony appearance are usually a result of different biochemical characteristics of the organisms. Table 34.6 lists some of the selective media used to isolate GI pathogens.

Campylobacter jejuni

C. jejuni grows best at 42°C in an atmosphere of reduced oxygen concentration (5% to 10%), which makes them microaerophilic organisms. Laboratories may have special gas supplies and culture chambers to provide an optimal atmosphere for culturing this organism. *C. jejuni* colonies form a characteristic morphology described as “running” or “wet looking” on growth media. Microscopic examination of the organisms shows characteristic curved, gram-negative rods (see Fig. 34.7). This appearance helps differentiate *C. jejuni* from *Pseudomonas aeruginosa*, which can grow under similar environmental conditions.

Salmonella

In patients with typhoid fever, blood cultures are most likely to be positive in the first week of infection, whereas stool cultures are more likely to be positive in the third and fourth weeks of infection. In patients with nontyphoid *Salmonella* gastroenteritis, the organisms may be recovered from stool. Routine microbiologic media such as sheep blood agar (SBA)

Fig. 34.7 Gram stain of *Campylobacter* colony showing the typical microscopic morphology described as seagull wings.

and MacConkey (MAC) agar can be used. Highly selective media such as Hektoen enteric (HE) agar (Fig. 34.8) and xylose-lysine-deoxycholate (XLD) agar may also be used.

Shigella species

These bacteria are fragile and do not survive well outside the human host for long periods. Culture recovery is enhanced by rapid transport of the specimen to the microbiology laboratory and prompt processing of the specimen. Media that can successfully recover *Salmonella* spp. are also useful for the recovery of *Shigella* spp. (Fig. 34.9).

Escherichia coli

E. coli is a normal inhabitant of the human GI tract. Pathogenic *E. coli* have the same appearance as commensal *E. coli* in culture media. A few diagnostic tests help differentiate pathogenic from nonpathogenic *E. coli*. For example, many EHEC will not ferment sorbitol. These bacteria can be differentiated from sorbitol-fermenting *E. coli* with the use of a differential medium such as sorbitol MAC agar (Fig. 34.10). EIEC has morphology and biochemical reactions similar to those of *Shigella* spp.

Fig. 34.8 *Salmonella* colonies growing on Hektoen enteric agar showing black centers resulting from the production of hydrogen sulfide.

Fig. 34.9 *Shigella* colonies growing on Hektoen enteric agar showing clear green colonies.

Table 34.6 Selective media commonly used to recover diarrheal agents

Culture medium	Purpose	Characteristic morphology	
		Pathogens	Colon biota
MacConkey (MAC) agar	To recover Enterobacterales and other nonfastidious, gram-negative bacilli; inhibits gram-positive organisms and some fastidious gram-negative bacilli	<i>Salmonella</i> , <i>Shigella</i> spp. (with few exceptions); organisms appear clear and colorless	Lactose fermenters, such as <i>Escherichia coli</i> , <i>Klebsiella</i> spp., <i>Enterobacter</i> spp., and certain <i>Citrobacter</i> spp., appear dark pink to red. Delayed or slow lactose fermenters, such as <i>Citrobacter</i> spp., <i>Serratia</i> spp., and <i>Hafnia</i> spp., appear colorless in 24 hours and slightly pink after 24–48 hours; non-lactose fermenters, such as <i>Proteus</i> spp., <i>Providencia</i> spp., and <i>Morganella</i> spp., appear clear and colorless.
Hektoen enteric (HE) agar	Highly selective medium to recover primarily <i>Salmonella</i> and <i>Shigella</i> spp.; inhibits common colon biota; contains indicators to detect hydrogen sulfide (H ₂ S) production	<i>Salmonella</i> appears green to blue-green with black centers because of H ₂ S production; <i>Shigella</i> spp. appear green without black centers because they do not produce H ₂ S	Lactose fermenters, such as <i>E. coli</i> , are slightly inhibited and appear orange to salmon pink; <i>Proteus</i> spp. are slightly inhibited; small, clear colonies with black centers may appear.
Xylose-lysine-deoxycholate (XLD) agar	Differential and selective medium to isolate <i>Salmonella</i> and <i>Shigella</i> spp. from stool; inhibits most colon biota and most gram-positive bacteria; certain <i>Shigella</i> spp. (<i>S. dysenteriae</i> and <i>S. flexneri</i>) may be slightly inhibited	<i>Salmonella</i> appear red with black centers because of production of H ₂ S; <i>Salmonella</i> does not ferment lactose or sucrose but does ferment xylose, which is essential in decarboxylating lysine to cause the acid pH (yellow from sucrose fermentation) to revert to an alkaline pH (red from lysine decarboxylation) <i>Shigella</i> spp. do not ferment any of these carbohydrates and appear red or clear	Enterobacterales that may not be completely inhibited, such as <i>Proteus vulgaris</i> , appear yellow (from sucrose) with black centers; <i>Citrobacter freundii</i> , which produces H ₂ S, appears yellow with black centers because of inability to decarboxylate lysine; other intestinal biota that may grow will ferment one or all of the carbohydrates in this medium, resulting in yellow colonies.
<i>Campylobacter</i> blood agar (CAMPY-BA)	Enrichment-selective medium primarily to isolate and cultivate <i>Campylobacter</i> spp. from stool	<i>Campylobacter jejuni</i> appears pinkish gray, moist, and runny when incubated at 42° C	
Cefsulodin-irgasan-novobiocin (CIN) agar	Selective medium primarily to isolate and recover <i>Yersinia enterocolitica</i> and <i>Aeromonas</i> spp.; <i>Plesiomonas shigelloides</i> may also be recovered; inhibits most gram-positive cocci, except for enterococci, and most gram-negative bacilli, particularly the Enterobacterales	<i>Yersinia enterocolitica</i> produces colonies that look like bull's eyes; center is red and periphery appears colorless; <i>Aeromonas</i> species also ferment mannitol present in the medium, like <i>Yersinia</i> ; <i>P. shigelloides</i> does not	Except for <i>Pseudomonas aeruginosa</i> , <i>Citrobacter</i> , and <i>Serratia</i> , most colon biota are inhibited.
Thiosulfate–citrate–bile salts–sucrose (TCBS) agar	Highly selective medium to recover <i>Vibrio</i> spp., including <i>Vibrio cholerae</i> , from stool and food; inhibits most colon biota because of the high pH (preferred by vibrios) and high bile salts content; <i>Aeromonas</i> spp. may be recovered from this medium	TCBS contains sucrose, so sucrose-fermenting <i>Vibrio</i> spp. such as <i>V. cholerae</i> and <i>V. alginolyticus</i> produce yellow colonies; nonsucrose fermenters, such as <i>V. parahaemolyticus</i> and <i>V. vulnificus</i> , produce blue-green colonies	Inhibitory to most colon biota, except for occasional <i>Pseudomonas</i> isolates, which may also appear blue-green.
Cycloserine-cefoxitin-fructose agar (CCFA), anaerobic incubation required	Selective medium to isolate primarily <i>Clostridioides difficile</i> from stool of patients suspected of having antibiotic-associated diarrhea or pseudomembranous colitis; inhibits most colon biota, both gram-positive and gram-negative bacteria	<i>C. difficile</i> appears yellow because of fructose fermentation	Colon biota are inhibited.
Sorbitol MacConkey (SMAC) agar	Differential medium to detect sorbitol-negative <i>Escherichia coli</i> ; contains sorbitol instead of lactose	<i>E. coli</i> O157:H7 appears colorless; does not ferment sorbitol	Most appear pink.

Yersinia species

Yersinia spp. grow well at cooler temperatures (25°C). The use of certain selective media, such as cefsulodin-irgasan-novobiocin (CIN) agar, allows for rapid isolation of these species. *Y. enterocolitica* forms colonies with a deep red center and transparent periphery. Recovery of the organism is increased by placing fecal samples in isotonic saline and keeping them at 4°C before inoculation onto the selective medium.

Vibrio species

Vibrio spp. require highly selective media for recovery. If these pathogens are suspected, the initial stool specimen should be transported to the laboratory in Cary-Blair medium or a similar transport medium. The sample can then be inoculated on thiosulfate–citrate–bile salts–sucrose (TCBS) agar for maximal yield. This medium not only inhibits the normal colonic biota but also differentiates sucrose-fermenting from non-sucrose-fermenting *Vibrio* spp. (Fig. 34.11). The salt requirement for growth may also help differentiate *V. cholerae*

Fig. 34.10 Left, *Escherichia coli* O157:H7 growing on MacConkey agar. Right, *E. coli* O157:H7 on sorbitol MacConkey agar. *E. coli* O157:H7 does not ferment sorbitol, whereas most other *E. coli* serotypes do ferment sorbitol.

Fig. 34.11 *Vibrio vulnificus* growing on thiosulfate–citrate–bile salts–sucrose agar. *Vibrio vulnificus* is a nonsucrose-fermenting vibrio.

from more halophilic *Vibrio* spp. In certain areas, especially in regions where cholera is endemic, antisera are available to identify outbreak strains of *V. cholerae*.

Clostridioides difficile

C. difficile produces yellow, ground-glass colonies on cycloserine-cefoxitin-fructose agar. Culture is infrequently used to diagnose this pathogen because patients may be colonized with non-toxin-producing strains. Instead, stool specimens are often examined for the presence of the *C. difficile* toxins.

Treatment and prevention of diarrhea

The most important factor to consider when treating a patient with acute diarrhea is his or her hydration status. Volume depletion and electrolyte derangements are major causes of morbidity and mortality from diarrheal illnesses. Because patients lose electrolytes in diarrheal stools, rehydration cannot occur with water alone. The best hydration solution contains both glucose and sodium. Although most patients can be treated effectively with oral rehydration, some require IV infusion of an isotonic solution (e.g., 0.9% saline, 5% dextrose in 0.9% saline, Ringer's lactate).

Antimicrobial therapy is ineffective against the viral causes of gastroenteritis. Patients with viral gastroenteritis should be given supportive care, with adequate hydration. Measures should be taken to prevent the spread of the pathogen to others. In severe cases, antimicrobial agents may be used against some bacterial pathogens, such as *Salmonella*. However, in several cases, this may be associated with a longer period of shedding of the organism in the stool, placing other people at risk of contracting the disease. Treating infections caused by EHEC with antimicrobial agents may increase the chance of developing HUS.

Antimicrobial therapy can be effective in shortening the duration of illness associated with some of the intestinal parasites. Antidiarrheal medications such as diphenoxylate with atropine (Lomotil) or loperamide can be considered for patients with severe symptoms. However, antimotility agents are not recommended for invasive diarrhea. Studies show conflicting data, but these agents may increase the severity of invasive disease, likely because of an increased contact time of the pathogen with the intestinal wall. Antimotility agents are generally used for the treatment of enterotoxin-mediated diarrhea, viral gastroenteritis, or traveler's diarrhea. Bismuth subsalicylate (Pepto-Bismol) can be effective in shortening the course of traveler's diarrhea, especially when caused by ETEC. People traveling to areas with a high prevalence of GI pathogens should carry with them a short course of a macrolide such as azithromycin for self-treatment of traveler's diarrhea and antimotility agents. Although this may be effective in reducing the duration of illness, most cases of traveler's diarrhea are self-limiting, even without therapy.

Travelers to high-risk areas should be advised to drink only bottled beverages and avoid consuming ice and undercooked food. Examples of high-risk foods include salads, fruits, dips, and raw or partially cooked fish or shellfish. Foodborne illnesses are avoided by thoroughly cooking all meats and poultry and by thoroughly washing all fruits and vegetables with potable water. Ideally, fruits and vegetables should be

peeled before use. To prevent secondary infections, patients with acute gastroenteritis should practice careful handwashing and avoid preparing food for others. The CDC maintains a website with the most recent recommendations (<https://wwwnc.cdc.gov/travel/page/yellowbook-home-2020>).

Two pathogens have been effectively targeted by a vaccine to help decrease the burden of disease: rotavirus and *Salmonella* Typhi. Two vaccines are approved for use in the United States. The CDC recommends that travelers to a country where typhoid is common should consider being vaccinated. The vaccine's efficacy in preventing diarrheal illness ranges from 50% to 80%. However, immunity produced by the vaccine wanes after a few years.

POINTS TO REMEMBER

- Factors that predispose patients to diarrheal illnesses include lack of clean drinking water, travel to endemic countries, history of GI disease, immunocompromised state, and medication intake.
- Travel history and a detailed dietary history provide significant information when determining the cause of diarrheal disease. Certain foods such as meat, shellfish, and poultry serve as vehicles of foodborne disease.
- Foodborne diseases are transmitted and acquired by ingestion of contaminated food and beverages.
- Clinical presentations can be characterized as enterotoxin-mediated diarrhea, invasion of bowel mucosa, or invasion with lymphatic or metastatic spread of infection.
- Food poisoning may be caused by chemical intoxications from fish or shellfish consumption, as well as bacterial toxins.
- Appropriate laboratory diagnosis may include the use of direct microscopy and selective culture media to recover and identify the suspected causative agent.

LEARNING ASSESSMENT QUESTIONS

1. What are the major host defense mechanisms located in the stomach? The small bowel? The colon?
2. What are the key elements to obtain in the history when interviewing a patient with diarrheal illness?
3. What initial laboratory findings aid in the diagnosis of acute diarrhea?
4. Which viruses, usually not associated with diarrheal illness in immunocompetent patients, may result in diarrhea in patients with acquired immunodeficiency syndrome (AIDS)?
5. How is the workup of diarrhea in an immunocompromised patient different from that in a healthy host?
6. Which parasite may cause a bloody diarrhea and disseminated infection sometimes resulting in liver abscesses?
7. What are some toxin-mediated forms of illness associated with fish and shellfish?
8. What are some life-threatening complications associated with bacterial diarrheal infections?
9. Which diarrheal infection is associated with prior antimicrobial use?
10. Which serotypes of *Vibrio cholerae* are associated with epidemic diarrhea?
11. How can travelers avoid diarrhea?
12. Which virus causes an acute self-limiting diarrheal illness that is highly contagious through contaminated food, water, fomites, or person-to-person contact and is associated with vomiting and low-grade fever?
 - a. Astroviruses
 - b. Rotaviruses
 - c. Norovirus
 - d. Enteric arenaviruses
13. A male patient and his family drove to the Florida coast and ate an oyster dinner. A couple of days later, the patient arrives at the emergency department with a fever, bullous skin lesions, and diarrhea. He is extremely ill and appears septic. The microbiologist notices curved, gram-negative rods on the stool Gram-stained smear. What is the most probable organism causing this condition?
 - a. *Yersinia enterocolitica*
 - b. *Vibrio vulnificus*
 - c. *Campylobacter jejuni*
 - d. *Vibrio cholerae*
14. Which diarrheal pathogen can produce a disease that can lead to hemolytic-uremic syndrome?
 - a. Enterohemorrhagic *Escherichia coli* (EHEC)
 - b. Enteroinvasive *E. coli* (EIEC)
 - c. Enteropathogenic *E. coli* (EPEC)
 - d. Enterotoxigenic *E. coli* (ETEC)
15. Although uncommon, which of the following intestinal parasite may cause metastatic disease and produce liver abscesses?
 - a. *Giardia lamblia*
 - b. *Entamoeba histolytica*
 - c. *Microsporidia*
 - d. *Cryptosporidium*
16. A patient who complains of sharp back pain is suspected to have cholecystitis. The patient is taken to surgery, and the infected gallbladder is removed. Exudate from the gallbladder is sent to the laboratory for culture. Which of the following organisms would you try to recover in an infected gallbladder?
 - a. *Escherichia coli* O157:H7
 - b. *Yersinia enterocolitica*
 - c. *Shigella* spp.
 - d. *Salmonella* spp.
17. A 15-year-old female patient is admitted to the hospital because of lower quadrant pain and a fever of 102° F. The patient's white blood cell count is 12,000/mm³ with 75% neutrophils and 6% bands. The clinical diagnosis is presumed acute appendicitis. At surgery, the appendix is grossly normal, but enlarged mesenteric lymph nodes are noted. One of these is excised and sent to the laboratory for culture. Which organism would most likely produce this clinical picture?
 - a. *Vibrio parahaemolyticus*
 - b. *Yersinia enterocolitica*
 - c. *Shigella* spp.
 - d. *Salmonella* spp.
18. A 30-year-old male patient served barbecued chicken for dinner with friends during a Sunday football game. On Tuesday following the event, the patient and a few of his guests develop fever and diarrhea. Microscopic stool

studies show red blood cells, leukocytes, and a very distinct microscopic morphology of the etiologic agent that can be described as “seagull wings.” After several days, the patient and his guests recovered without complications. Based on the preliminary findings, which bacterial agent should you suspect?

- a. *Campylobacter jejuni*
- b. *Yersinia enterocolitica*
- c. *Shigella* spp.
- d. *Salmonella* spp.

19. A 2-year-old female patient who attends a daycare center is admitted to the hospital with a 3-day history of fever, abdominal pain and cramping, watery diarrhea, and vomiting. The stool shows gross blood and pus. Stool culture grows many lactose-negative colonies on MacConkey agar after 24 hours of incubation. Which of the following organisms is the most probable identification of the isolate?

- a. *Providencia stuartii*
- b. *Yersinia enterocolitica*
- c. *Shigella* sp.
- d. *Salmonella* sp.

20. A patient with a history of alcoholism is seen in the emergency department with symptoms of septicemia and bullous skin lesions. He reported ingestion of raw oysters 24 hours earlier. Which of the following organisms should you suspect as the causative agent?

- a. *Shigella sonnei*
- b. *Yersinia enterocolitica*
- c. *Vibrio vulnificus*
- d. *Campylobacter jejuni*

Bibliography, 903

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Explain how cerebrospinal fluid (CSF) is produced and distributed in the central nervous system (CNS).
2. Describe the characteristics of normal CSF.
3. Describe the collection, transportation, and processing of CSF samples.
4. For each pathogen associated with meningitis, correlate one host-related risk factor and one virulence-related risk factor.
5. Identify the common bacterial, fungal, and parasitic pathogens associated with brain abscesses.
6. Correlate fungi that typically cause meningitis.
7. Compare the virulence and host factors of two fungi that typically cause intracerebral lesions.
8. Associate two viruses associated with meningitis, encephalitis, and paralysis.
9. Correlate cerebrospinal fluid laboratory results (i.e., glucose, protein, cell counts) with likely agents causing meningitis.

^aThis chapter was prepared by the author in her private capacity. No official support or endorsement by the U.S. Food and Drug Administration is intended or implied.

10. Justify rapid processing of CSF and other specimens from the CNS for the evaluation of infectious agents.

KEY TERMS

Aseptic meningitis

Brain abscess

Central nervous system (CNS)

Cerebrospinal fluid (CSF)

Encephalitis

Meningismus

Meningitis

Meningoencephalitis

Pleocytosis

Primary amebic meningoencephalitis

Tuberculous meningitis

Case in point

A 3-year-old male patient with a recent history of acute otitis media was brought to the emergency department. On examination, he was found to be febrile with an oral temperature of 103°F (39.4°C), reference range 95.9°F (35.5°C) to 99.5°F (37.5°C), and lethargic. No rash was present. A complete blood count revealed leukocytosis with a total leukocyte count of 21,000/μL (reference range 5000 to 10,000/μL) with a left shift. Lumbar puncture revealed a cloudy cerebrospinal fluid (CSF) with a leukocyte cell count of 210/μL (reference range ≤5) with 85% neutrophils. The CSF glucose level was decreased (15 mg/dL), and the CSF protein level was increased (450 mg/dL). The patient was given ceftriaxone intravenously, and the CSF sample was sent to the microbiology laboratory for Gram stain and culture. The Gram-stained smear of the cytocentrifuged CSF revealed a moderate number of intracellular, gram-positive cocci in pairs. Culture of the CSF grew a mucoid strain of *Streptococcus pneumoniae*. Susceptibility testing was performed, and the following minimal inhibitory concentrations (MICs) were obtained: penicillin 2.0 μg/mL, ceftriaxone 0.012 μg/mL, and vancomycin 0.25 μg/mL.

Issues to consider

After reading the patient's case history, consider:

- Host-related risk factors in the patient
- Bacterial, fungal, or parasitic agents that may be involved based on the clinical presentation, and possible sources of infection

- Physical, chemical, and cellular features of CSF
- Specimen collection, transport, and processing for maximum recovery of the causative agent
- Rapid diagnostic methods that can facilitate the presumptive diagnosis and initiation of therapy

Infections of the **central nervous system (CNS)** are serious and potentially life-threatening. These infections may be caused by bacteria, viruses, fungi, or parasites. The primary health care provider arrives at a presumptive diagnosis based on the patient's age, presence of risk factors, clinical presentation, physical examination, local epidemiology of CNS infections, **cerebrospinal fluid (CSF)** analysis, and radiologic studies. The specific causative agent is identified through laboratory testing.

The epidemiology of bacterial meningitis has changed over the decades. Since the introduction of vaccination against *Haemophilus influenzae* type b in the 1980s, there has been a dramatic reduction in the incidence of meningitis caused by this organism. In the United States, *Streptococcus pneumoniae* has become the leading cause of bacterial meningitis among children younger than 5 years of age. With the inclusion of pneumococcal vaccination in the routine immunization schedule for children, universal screening of pregnant women for group B *Streptococcus* (GBS), and the availability of newer meningococcal vaccines, there has been a further reduction in the incidence of bacterial meningitis.

Pneumococci cause over 50% of all cases of bacterial meningitis in the United States. An estimated 3000 to 6000 cases of pneumococcal meningitis occur each year. Before routine use of the pneumococcal conjugate vaccine, children younger than 1 year of age had the highest rates of pneumococcal

meningitis, approximately 10 cases per 100,000 population. The incidence of meningococcal meningitis is higher in sub-Saharan Africa (the so-called *meningitis belt*), extending from Senegal in the west to Ethiopia in the east. Although mortality rates have decreased as a result of improved medical management of CNS infections, in some children, developmental delay, learning disabilities, and behavioral problems may still occur. Thus CNS infections are a cause of immediate as well as long-term health concerns.

This chapter discusses the following:

- The interplay of host-related risk factors and virulence factors associated with the pathogens
- Characteristics of the CSF in CNS infections
- Microbial agents of CNS infections
- Laboratory diagnosis of CNS infections

General concepts related to infections of the central nervous system

Anatomic organization

The CNS encompasses the brain, spinal cord, and cranial nerves, but not the peripheral nerves (Fig. 35.1). The brain and spinal cord are protected by the skull and vertebral column, respectively, and three layers of meninges: the dura mater, arachnoid mater, and pia mater. The dura mater is a thick, fibrous, white membrane that is firmly adherent to the overlying skull. Below the dura mater is the arachnoid mater, followed by the pia mater.

Fig. 35.1 Components of the central nervous system and flow pattern of cerebrospinal fluid.

The subarachnoid space between the arachnoid mater and pia mater is occupied by surface blood vessels and CSF. CSF is produced by filtration and secretion from specialized capillary tufts of the choroid plexus in the four ventricles of the brain. CSF flows from the two lateral ventricles to the third ventricle and enters the fourth ventricle via the aqueduct of Sylvius. From here, CSF enters the basal cisterns and circulates over the cerebellum and convexities of the cerebral hemispheres. CSF is absorbed primarily by the arachnoid villi through tight junctions of the endothelium.

Cerebrospinal fluid characteristics

CSF is a clear, colorless, and sterile fluid. In normal adults, CSF volume ranges from 90 to 150 mL, the protein concentration is 15 to 45 mg/dL, and the glucose concentration is 40 to 80 mg/dL (ratio of CSF glucose to serum glucose is 0.6). In normal adults, CSF contains 0 to 7 leukocytes per microliter, with a differential count of 60% to 80% lymphocytes, 10% to 40% monocytes, and 0% to 15% neutrophils. Compared with adults, normal newborns have higher CSF concentrations of protein (15 to 150 mg/dL), glucose (30 to 120 mg/dL), and leukocytes (0 to 30 per milliliter), with a greater percentage of monocytes and neutrophils. The paucity of leukocytes and protein (including immunoglobulins) in CSF provides little initial defense against invading organisms. Infections of the CNS are frequently, but not invariably, associated with an increase in CSF cell count (**pleocytosis**) and alterations in glucose and protein levels.

Host-pathogen relationships

Infection results from the complex interplay among the host, organism, and environment. Host risk factors that predispose to infection include extremes of age; nutritional and immunologic status; comorbidities, such as alcoholism, diabetes mellitus, malignancy, renal failure, and head trauma; and neurosurgical procedures. Structural components of the organism, such as capsule, pili, and fimbriae, which mediate adherence to respiratory tract epithelial cells, play an important role in meningeal infection. Additionally, the bacterial capsule can resist neutrophil phagocytosis and complement-mediated bactericidal activity, thus enhancing survival in the bloodstream. Host defenses include the presence of mucosal immunity mediated via immunoglobulin A (IgA) antibody, complement activation, and the presence of organism-specific antibodies. The CNS is normally a sterile site.

Central nervous system infections

Meningitis

Acute **meningitis** is commonly caused by bacteria (e.g., *S. pneumoniae*, *Neisseria meningitidis*, *H. influenzae*, *Listeria monocytogenes*) or viruses (e.g., enteroviruses [EVs], herpesvirus, mumps virus). Less commonly, it is caused by other organisms, such as fungi (e.g., *Cryptococcus neoformans* and *Cryptococcus gattii*), spirochetes (e.g., *Treponema pallidum*, *Borrelia burgdorferi*), protozoa (e.g., *Naegleria fowleri*), or helminths (e.g., *Angiostrongylus cantonensis*). Patients with acute meningitis usually have fever, headache, vomiting,

photophobia, and altered mental status. In infants and children, irritability, restlessness, and poor feeding may be the only signs of meningitis. Untreated meningitis can result in obtundation, coma, and death.

Bacterial meningitis

The likely causative agents of bacterial meningitis depend on the age of the patient (Box 35.1) and on host factors, such as immune status, presence of a CSF leak, or presence of a foreign body, such as a ventriculoperitoneal shunt.

Pathogenesis

Bacterial infection of the leptomeningeal space, the space between the arachnoid membrane and pia mater, can occur from a distant focus via the bloodstream or by direct invasion from a contiguous focus of infection (e.g., mastoid or paranasal sinuses) or as a result of neurosurgical procedures. Most commonly, infection or colonization of the respiratory tract is followed by invasion of blood from a respiratory focus and seeding of the meninges. Once in CSF, bacteria replicate, release bacterial components, and cause an inflammatory reaction.

S. pneumoniae, a gram-positive diplococcus, is the most common cause of meningitis in adults and children (Fig. 35.2). Of more than 90 serotypes, only a few serotypes—including 4, 6B, 9V, 14, 18C, 19F, and 23F—accounted for most cases of invasive childhood pneumococcal infections in the United States before the implementation of routine immunization in infants with the heptavalent pneumococcal conjugate vaccine (PCV7). Serotype 19A has emerged as the most common cause of invasive disease and the serotype most associated

Fig. 35.2 Direct smear of acute bacterial meningitis in an adult showing the lancet-shaped, gram-positive diplococci characteristic of *Streptococcus pneumoniae*. The polysaccharide capsule produces a prominent halo around organisms (Gram stain, noncytocentrifuge preparation, $\times 1000$).

Fig. 35.3 Direct smear of the cerebrospinal fluid from a high school student showing clusters of gram-negative diplococci consistent with *Neisseria meningitidis* within polymorphonuclear leukocytes. Note the increased cellularity of the smear in this cytocentrifuge preparation (Gram stain, $\times 1000$).

with resistance in PCV7-immunized children. Patients with sickle cell anemia, those who have asplenia, and those with malignancy, malnutrition, and chronic renal or liver disease are more likely to develop serious pneumococcal disease.

Three pneumococcal conjugate vaccines are available for use in adults and children in the United States: (1) the 13-valent pneumococcal conjugate vaccine (PCV13), which is composed of purified polysaccharides of 13 serotypes conjugated to a nontoxic variant of diphtheria toxin carrier protein, CRM197; (2) the 15-valent conjugate vaccine (PCV15); and (3) the 20-valent conjugate vaccine (PCV20). A fourth vaccine is the 23-valent pneumococcal polysaccharide vaccine (PPSV23); it is composed of 23 purified capsular polysaccharides. The Centers for Disease Control and Prevention recommends PCV13 for children younger than 2 years of age.

H. influenzae type b, a gram-negative coccobacillus, is an important cause of bacterial meningitis in children. In addition to meningitis, it can cause otitis media, pneumonia, and epiglottitis. *H. influenzae* was previously the most common cause of bacterial meningitis, especially in young children. Most cases were caused by the capsular type b strains. Since the adoption of the routine use of conjugate vaccines against *H. influenzae* type b, there has been a marked reduction in the number of cases of *H. influenzae* meningitis. In developing countries with limited vaccine coverage, however, it continues to be an important cause of bacterial meningitis. In the United States, the proportion of invasive infections caused by strains of *H. influenzae* not type b have increased.

N. meningitidis, a gram-negative diplococcus (Fig. 35.3), is classified into 13 serogroups based on antigenically distinct, non-cross-reactive capsular polysaccharides. Serogroups A, B, C, X, Y, and W135 account for most cases of meningococcal disease throughout the world. Serogroups B, C, and Y account for most cases in Europe and the United States. Disease attributable to serogroup A is seen in Asia and Africa but is rare in industrialized countries. Disease caused by serogroups A and C can occur in epidemics. Outbreaks have also been reported with the W135 serogroup. Several clusters of serogroup B meningococcal disease have occurred on college campuses in the United States. Serogroup X causes a substantial number of cases of meningococcal disease in parts of Africa but is rare on other continents. Individuals who are deficient in terminal complement components (C5–C9) or properdin are

at a higher risk for meningococcal infections. In the United States, three quadrivalent conjugate meningococcal vaccines are licensed for use in children and adults against serogroups A, C, Y, or W, and two recombinant serogroup B are licensed for people 16 to 23 years of age.

L. monocytogenes is a gram-positive rod. Infection by this organism is usually seen in pregnant women, neonates, older adults, persons with alcoholism, and persons with impaired cell-mediated immunity. Outbreaks of *Listeria* infection have been associated with the consumption of contaminated coleslaw, milk, ice cream, and cheese. Patients with meningitis caused by *Listeria* have low CSF leukocyte counts, with a predominance of lymphocytes.

Streptococcus agalactiae (or GBS) is a gram-positive coccus that is often isolated from rectal or vaginal cultures of asymptomatic pregnant women. Early-onset GBS disease usually occurs within the first 24 hours of life and is not commonly associated with meningitis (5% to 10% of cases). Late-onset disease, which typically occurs at 3 to 4 weeks of age (range 7 to 89 days), commonly manifests as occult bacteremia or meningitis (approximately 30% of cases). Approximately 50% of survivors of early- or late-onset meningitis have long-term neurologic sequelae. Hospital transmission via the hands of health care workers has been described. Most cases of neonatal meningitis are caused by serotype III. Risk factors for GBS infection in adults include age older than 60 years, diabetes mellitus, and underlying malignancy.

Aerobic gram-negative bacilli, such as *Escherichia coli*, *Klebsiella* spp. (Fig. 35.4), *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, *Serratia* spp., and *Salmonella*, can also cause meningitis. In addition to neonates, older adults, patients with head trauma, or those who have undergone neurosurgical procedures are also at risk of meningitis caused by these organisms. Most strains of *E. coli* that cause meningitis possess the K1 antigen.

Other bacteria

Meningitis caused by *Staphylococcus aureus*, coagulase-negative staphylococci, or *Abiotrophia* and *Granulicatella* spp. usually occurs in patients who have undergone recent neurosurgical procedures or in those with CSF shunts. Meningitis caused by enterococci or group A streptococci are not commonly seen. Meningitis caused by anaerobic streptococci, *Bacteroides* spp.

Fig. 35.4 Direct smear of posttraumatic, acute bacterial meningitis showing numerous intracellular and extracellular gram-negative bacilli with the prominent capsules characteristic of *Klebsiella pneumoniae* (Gram stain, cytocentrifuge preparation, $\times 1000$).

Fig. 35.5 Direct smear of cerebrospinal fluid from a newborn patient born to a woman with amnionitis secondary to premature rupture of the membranes. Numerous short, gram-negative bacilli in chains consistent with a *Bacteroides* sp. are seen. The organism could easily be confused with a *Streptococcus* sp. if the Gram stain were improperly decolorized (Gram stain, noncytocentrifuge preparation, $\times 1000$).

(Fig. 35.5), and *Fusobacterium* spp. is uncommon and is usually associated with a concurrent **brain abscess** or a contiguous focus of infection.

Shunt infections

Generally, CSF shunts are placed in patients with hydrocephalus or other CNS lesions that interfere with the flow of CSF. The proximal end of the shunt is in the cerebrospinal space, and the distal end is in the peritoneal, pleural, or vascular space. Patients with shunts are at risk of developing infections. Staphylococci account for two thirds of CSF shunt infections, with coagulase-negative staphylococci being the most common, followed by *S. aureus*. Gram-negative organisms, such as *E. coli*, *Klebsiella* spp., and *Proteus* spp., also can cause CSF shunt infections. An increasing incidence of CSF shunt infections from *Cutibacterium acnes* has been reported. Immunosuppressed patients can develop CSF shunt infections with *Candida* spp. CSF shunts terminating in the peritoneal cavity have a greater risk of infection with gram-negative organisms; mixed infections are seen when the catheter perforates a hollow viscus.

Viral infections

Case study

A 36-year-old male patient with human immunodeficiency virus (HIV) infection presented to the emergency department with complaints of inability to urinate for 3 days. He also reported numbness and weakness in his right leg for 7 months, a 25-lb weight loss, and fecal incontinence. Physical examination showed that he was afebrile, dehydrated, and emaciated, with bilateral lower extremity weakness and decreased deep tendon reflexes. Lesions of Kaposi sarcoma, thrush, and perianal herpetic vesicles were observed. Magnetic resonance imaging revealed no evidence of spinal cord compression, and a presumptive diagnosis of polyradiculopathy secondary to acquired immune deficiency syndrome (AIDS) was made. A lumbar puncture was performed. CSF showed an increased protein level (326 mg/dL) and a leukocyte count of 1720/mL, with 86% neutrophils.

Fig. 35.6 Cytocentrifuge preparation of cerebrospinal fluid in a case of aseptic meningitis. Lymphocytes are present, and in this case the background is bloody. No organisms are seen (Wright stain, $\times 200$).

Viruses are the most frequent cause of **aseptic meningitis**, a condition characterized by lymphocytic pleocytosis in CSF and lack of an identifiable causative agent after routine stains and culture of CSF (Figs. 35.6 and 35.7). The most common viruses producing aseptic meningitis include EVs and herpesviruses. Less common causes of viral meningitis include mumps virus, lymphocytic choriomeningitis virus (LCMV), and HIV (Box 35.2). Viral pathogens colonize various mucosal surfaces in the body, such as the respiratory and gastrointestinal (GI) tracts. Some viruses (e.g., EVs, adenoviruses, and parvoviruses) can resist inactivation by gastric acid. After initial replication at the site of mucosal colonization, viremia develops, followed by invasion of the CNS. Early viral infections may show a predominance of neutrophils in CSF, but the pleocytosis rapidly progresses to a lymphocytosis.

Determination of a specific causative virus associated with a CNS infection is difficult because of the following: (1) a large number of different viruses involve the CNS; (2) viruses may come from endogenous reactivation or exogenous infection; (3) many viruses produce a spectrum of neurologic illnesses; and (4) the magnitude of any neurologic illness resulting from viruses varies based on the age and immune status of

Fig. 35.7 Cytocentrifuge preparation of cerebrospinal fluid in meningitis resulting from tularemia. Reactive lymphocytes with monocytoid features are the only clue that this is not a viral infection. No organisms are seen. Cultures were positive (Wright stain, $\times 400$).

BOX 35.2 Viral agents involving the central nervous system

Enteroviruses

Coxsackieviruses A and B
Echoviruses
Parechoviruses
Polioviruses
Eastern equine encephalitis
Western equine encephalitis
Venezuelan equine encephalitis
St. Louis encephalitis virus
La Crosse virus
Colorado tick fever virus

Herpesviruses

Herpes simplex viruses 1 and 2
Epstein-Barr virus
Cytomegalovirus
Varicella-zoster virus

Others

Human immunodeficiency virus
Mumps virus
Dengue virus
Nipah virus
Rabies virus

the patient as well as other undefined factors. The determination of a specific viral cause can often be made with a careful patient history; selected serologic tests (e.g., determination of virus-specific immunoglobulin M [IgM] or of a fourfold or greater increase in antibody titer between acute-phase and convalescent-phase sera); a viral culture or polymerase chain reaction (PCR) assay for selected viruses; and tissue biopsy for routine light microscopy, immunofluorescence, or ultrastructural studies. Viruses isolated from body sites other than the CNS may be implicated in CNS syndromes. Appropriate specimens for culture include nasopharyngeal swabs, urine, stool, tissue, and occasionally blood.

Enteroviruses

EVs belong to the genus *Enterovirus* within the family Picornaviridae and include polioviruses, coxsackieviruses A and B, rhinoviruses, and echoviruses. EVs that are frequently associated with neurologic illness include coxsackievirus B and echoviruses. Although many different serotypes can cause meningitis, coxsackievirus serotypes A6, A9, B2, B3, B4, and B5; EV 71; and echovirus serotypes 4, 6, 9, 11, 16, 18, and 30 are the most common. In 2014, there were several reports of paralysis and neurologic illness in children caused by infection with EV D68.

In temperate climates, enteroviral infections are more common in summer, but in subtropical areas, no marked seasonality is observed. These infections are acquired via the fecal-oral route. Most cases of enteroviral meningitis are uncomplicated, with signs and symptoms resolving in 2 to 7 days. Most poliovirus infections are asymptomatic or cause aseptic meningitis, but a small proportion of infections progress to destruction of motor neurons in the anterior spinal cord, resulting in paralysis. Although the incidence of paralytic poliomyelitis has decreased dramatically since effective vaccines became available, outbreaks continue to occur in some parts of the world. A paralytic case was reported in 2022 in New York, the first case in the United States since 2013. The patient had no history of vaccination against poliovirus and was infected with a revertant or novel oral polio vaccine 2. A similar strain was isolated in London sewage also in 2022. Parechoviruses (PeVs) are members of the genus *Parechovirus* within the family Picornaviridae. PeV types 1 and 3 are associated with neonatal sepsis and meningitis.

Arboviruses

Arboviruses include a group of viruses transmitted by vectors, such as mosquitoes, ticks, sandflies, and other biting arthropods. Several of these viruses cause encephalitis, but aseptic meningitis and meningoencephalitis can also occur. The common arboviruses causing aseptic meningitis include the St. Louis encephalitis (SLE) virus, La Crosse (LAC) virus, Eastern equine encephalitis (EEE) virus, Western equine encephalitis (WEE) virus, West Nile virus (WNV), and Dengue virus (DENV). Neurologic manifestations of dengue infection (encephalitis, encephalopathy, occasionally meningitis) have been reported in multiple countries in infants, children, and adults. Japanese encephalitis virus, a mosquito-borne flavivirus, is endemic in parts of Asia. It can produce a severe encephalitis characterized by coma, seizures, paralysis, and abnormal movements. About one third of patients die, and serious sequelae are common in a significant proportion of survivors. In Mediterranean countries, Toscana virus, which belongs to the family Bunyaviridae, has also been identified as an important causative agent of acute meningitis and meningoencephalitis.

Mumps virus

The mumps virus, a member of the family Paramyxoviridae, commonly causes parotitis (infection or inflammation of the parotid salivary glands). Aseptic meningitis is the most common neurologic complication. Symptoms of meningitis occur in up to 30% of patients with mumps parotitis within 4 to 10 days of illness. Occasionally, meningeal symptoms can precede parotitis by up to 7 days. Infection of the CNS is usually self-limiting and associated with complete recovery. Due to routine vaccination, mumps and its complications

are rare in developed countries. Mumps virus vaccine is an attenuated vaccine that is usually given as part of the combined measles-mumps-rubella vaccine.

Herpesvirus

Herpesviruses are DNA viruses. They include herpes simplex virus (HSV)-1, HSV-2, Epstein-Barr virus (EBV), cytomegalovirus (CMV), varicella-zoster virus (VZV), human herpesvirus (HHV)-6, HHV-7, and HHV-8. Herpesviruses account for 0.5% to 3% of all cases of aseptic meningitis. Although aseptic meningitis can occur with any of these viruses, only meningitis associated with HSV is common. The clinical outcome in patients with aseptic meningitis resulting from herpesvirus is indistinguishable from that of other causes, and the outcome is uniformly good. It is important, however, to differentiate between HSV encephalitis, a potentially fatal disease, and the self-limiting HSV aseptic meningitis. Infants born to mothers with genital herpes are at risk for serious infection. HSV is associated with Mollaret's meningitis, also called recurrent lymphocytic meningitis, a recurring form of meningitis.

Influenza

Influenza viruses are members of the family Orthomyxoviridae. In children younger than 5 years of age, CNS involvement (mainly presenting as encephalitis) is associated with influenza A virus and less frequently with influenza B virus.

Human immunodeficiency virus

HIV is a member of the family Retroviridae. Meningitis associated with HIV infection may occur as part of the primary infection or may occur later in the course of the infection. Patients with acute infection usually have aseptic meningitis as part of the mononucleosis-like syndrome. Patients presenting with chronic meningitis often have other associated symptoms, such as cranial neuropathies. In addition, patients with HIV can present with CNS involvement attributable to opportunistic pathogens.

Mycobacterial infections

Although uncommon, the most common mycobacterial infection of the CNS is tuberculous meningitis caused by *Mycobacterium tuberculosis*. Other mycobacteria associated with CNS infections include *Mycobacterium bovis*, *Mycobacterium avium*, *Mycobacterium intracellulare*, *Mycobacterium kansasii*, *Mycobacterium fortuitum*, *Mycobacterium abscessus*, and *Mycobacterium africanus*. Mycobacteria are acid-fast bacilli with a thick cell wall containing lipids, peptidoglycans, and arabinomannans. The bacilli enter the body through respiratory droplets and multiply in the alveolar spaces or macrophages. Spread to extrapulmonary sites occurs via the blood stream.

HIV infection is a risk factor for tuberculous meningitis. **Tuberculous meningitis** results when the brain tubercle ruptures into the subarachnoid space. Both the meninges and the brain itself are frequently involved, with a resulting thick exudate, especially at the base of the brain. The clinical presentation of tuberculous meningitis is subacute and includes fever, headache, **meningismus**, and mental changes. Meningismus, also called meningism, is a set of symptoms caused by non-meningitis irritation of the meninges usually associated with acute febrile illness. It is typically characterized by neck stiffness, photophobia, and headache. Vomiting and other signs of increased intracranial pressure may occur.

Spirochetal infections

The two spirochetes associated with CNS infection are *T. pallidum* subsp. *pallidum* and *B. burgdorferi*. *T. pallidum* subsp. *pallidum*, the causative agent of syphilis, enters the CNS during early infection and can be isolated from CSF in patients with primary syphilis. Many cases of neurosyphilis are reported in patients with HIV infection. Manifestations of neurosyphilis can occur at any stage of infection, especially in patients with HIV infection. Syphilitic involvement of the CNS can take one of four forms: syphilitic meningitis, meningovascular syphilis, parenchymatous neurosyphilis, and gummatous neurosyphilis.

Involvement of the CNS can occur in patients with Lyme borreliosis. It is usually seen in patients with early disseminated disease and is less likely during late disease. Not all cases of Lyme meningitis are preceded by the characteristic erythema migrans rash. In addition to signs of meningeal irritation, some patients with Lyme meningitis can have other neurologic manifestations of Lyme disease, such as cranial nerve neuropathy (commonly cranial nerve VII) and radiculoneuritis.

Fungal Infections

Case study

A 52-year-old male patient arrived at an emergency department in a disoriented and poorly responsive state and with labored breathing. The patient's history included poorly controlled diabetes and chronic obstructive pulmonary disease secondary to cigarette smoking. Current medications included oral steroids for pulmonary disease. On physical examination, the patient was febrile, lethargic, and in respiratory failure. A lumbar puncture was performed. Direct smear of the CSF using calcofluor white reagent showed encapsulated budding yeasts. Despite aggressive therapy with amphotericin B and 5-flucytosine, the patient's condition failed to improve, and he died on the third day of hospitalization.

Fungi are uncommon causes of CNS infections ([Box 35.3](#)). The risk factors for CNS fungal infections include immunocompromised state, organ transplantation, and diabetes. *Aspergillus* and *Cryptococcus* species are the most common etiologic agents in immunosuppressed patients. Other etiologic agents include *Coccidioides immitis*, *Histoplasma capsulatum*, and *Blastomyces dermatitidis*. Concurrent infections with *C. neoformans* and *H. capsulatum* have been reported in immunocompromised persons. Recent outbreaks caused by *Cryptococcus gattii* have been reported in the Pacific Northwest of the United States in previously healthy individuals. Rare cases of meningeal sporotrichosis caused by *Sporothrix schenckii* have been reported. The clinical presentation is usually of chronic meningitis. The white blood cell count is usually moderately elevated, with a predominance of lymphocytes. A predominance of eosinophils may occur in infections caused by *Coccidioides* organisms.

An outbreak of fungal meningitis and other infections was reported among patients who received injections of contaminated preservative-free methylprednisolone acetate solution. In addition to fungal meningitis, localized spinal or paraspinal infections, such as epidural abscess and arachnoiditis, and infections associated with injections in joints, were reported. The predominant fungus identified in patients was *Exserohilum rostratum*. One patient, the index case, had a laboratory-confirmed *Aspergillus fumigatus* infection.

BOX 35.3 Fungal organisms involving the central nervous system

Common

Cryptococcus neoformans
Coccidioides immitis

Uncommon

Histoplasma capsulatum
Candida spp.
Cryptococcus gattii
Aspergillus spp.
Blastomyces dermatitidis

Rare

Paracoccidioides brasiliensis
Pseudallescheria boydii
Mucorales (*Mucor*, *Rhizopus*, *Absidia*, and *Cunninghamella* spp.)
Sporothrix schenckii
Trichosporon beigelii
Penicillium spp.
Fusarium spp.
Alternaria spp.
Curvularia spp.
Acremonium spp.
Fonsecaea spp.
Bipolaris spp.
Drechslera biseptata
Exserohilum rostratum

Fig. 35.8 Cytocentrifuge preparation of cerebrospinal fluid showing a single yeast with narrow-based budding and a prominent surrounding capsule characteristic of *Cryptococcus neoformans*. Cryptococcal meningitis in partially immunocompetent hosts may show only rare organisms mixed with an inflammatory background of lymphocytes, monocytes, and eosinophils (Wright stain, $\times 1000$).

C. neoformans is an encapsulated basidiomycetous yeast. It can spread hematogenously to the CNS from pulmonary foci and cause chronic meningitis, particularly in patients with AIDS. There are two varieties of *C. neoformans*: *C. neoformans* var. *neoformans* and *C. gattii* (formerly known as *C. neoformans* var. *gattii*). *C. neoformans* var. *neoformans* is the major isolate in patients with AIDS. *C. gattii* human infections have been reported in North America, South America, and Australia. In the United States, most cases have been reported in the Pacific Northwest and California. The number of organisms in the CSF may be small in immunocompetent patients (Fig. 35.8) but large in immunosuppressed patients (Fig. 35.9).

Fig. 35.9 Cryptococcal meningitis in immunosuppressed hosts may show numerous organisms and scarce or absent inflammation. Note the variation in size, variable Gram staining, and narrow-based budding. The organisms are evenly spaced because of their abundant polysaccharide capsules (Gram stain, cytocentrifuge preparation, $\times 400$).

C. immitis and *B. dermatitidis* are dimorphic fungi that can cause chronic meningitis. Inhalation of conidia results in pulmonary infection, which may spread to the CNS via the blood stream and cause an abscess or fulminant meningitis. Infections caused by *C. immitis* are limited to endemic regions, mainly the southwestern United States, Mexico, and Central and South America. *B. dermatitidis* is endemic in the Mississippi and Ohio river basins. In rare cases of disseminated histoplasmosis (*Histoplasma capsulatum*), involvement of the CNS is observed. Like *B. dermatitidis*, it is endemic in the Mississippi and Ohio river basins.

Candida spp. are a cause of fungal meningitis and cerebral abscesses. They are mainly seen in patients with invasive or disseminated candidiasis. Candidiasis may be acquired as a healthcare-associated infection in patients with indwelling catheters or those receiving prolonged antimicrobial therapy. CNS infection with *Candida* spp. can occur in patients with ventriculoperitoneal shunts. Patients with low peripheral blood neutrophil counts secondary to chemotherapy are at risk for candida infections. *Candida albicans*, *Candida tropicalis*, and *Candida parapsilosis* are the most commonly identified species.

Parasitic infections

Although uncommon, protozoa and helminths can invade the CNS and cause meningitis. Some parasites cause CNS lesions without obvious meningeal inflammation. They are discussed briefly in this section.

Protozoa

The free-living amebae that can infect humans include *N. fowleri*, *Acanthamoeba* spp., and *Balamuthia mandrillaris*. Trophozoites invade the nasal epithelium and migrate to the CNS via the olfactory nerve. *N. fowleri* can cause a rapidly progressive and almost always fatal **primary amebic meningoencephalitis**. *Acanthamoeba* spp. and *B. mandrillaris* usually cause granulomatous amebic encephalitis with a more insidious onset. *N. fowleri* is found in warm freshwater and moist soil. Most cases of infection have been associated with swimming in warm natural bodies of water. *Acanthamoeba* spp. are found in soil, freshwater, brackish water, and

sewage. No environmental sources have been identified for *B. mandrillaris*.

Cerebral malaria is an acute illness that occurs because of sequestration of the parasite *Plasmodium falciparum* in the CNS. It is characterized by changes in mental status, seizures, motor deficits, and coma. Human infection is initiated when the sporozoite stage of *P. falciparum* is injected into the bloodstream during mosquito feeding. Parasitized red blood cells develop knobs with cytoadherent surface properties, causing them to adhere to the endothelium of capillaries and venules in the brain.

Toxoplasma gondii is a coccidian, obligate, intracellular protozoan. Humans acquire infection by eating raw or undercooked meat containing tissue cysts or by contact with oocysts from feral or domestic cats. Organ transplant recipients may acquire toxoplasmosis from a donated organ. The seroprevalence of toxoplasmosis is higher in Europe and South America than in the United States. Sporozoites released from the ingested oocyst or tissue cysts invade the human small intestine, spread hematogenously, and invade cells of the viscera and possibly the brain. In immunocompromised patients, toxoplasmosis may result from primary infection or reactivation of a latent infection and commonly affects the CNS. CSF findings (Fig. 35.10) are nonspecific and include a mild lymphocytic pleocytosis and increased CSF protein level. The diagnosis of toxoplasmosis is usually serologic, although immunocompromised patients may not demonstrate a humoral immune response to the infection. In such cases, especially if there is a focal brain lesion, diagnosis can be obtained by brain biopsy. In patients with AIDS, the brain lesions have characteristic radiologic features; the diagnosis is often confirmed by clinical response to specific therapy.

Trypanosomes that infect humans include *Trypanosoma brucei* subsp. *gambiense*, *T. brucei* subsp. *rhodesiense*, and *Trypanosoma cruzi*. The first two are found predominantly in Africa. Humans are infected by the bite of tsetse flies. Infection with *T. brucei gambiense* results in a chronic meningoencephalitis more commonly known as *sleeping sickness*. CNS infection with *T. brucei rhodesiense* results in a more acute disease, often resulting in death. *T. cruzi*, the causative agent of Chagas disease, is found in Central and South America. In immunosuppressed patients, encephalitis caused by *T. cruzi* is observed.

Fig. 35.10 Touch preparation of brain tissue showing typical floret of *Toxoplasma gondii* trophozoites. The organisms are not typically seen in cerebrospinal fluid preparations (Wright stain, $\times 1000$).

Helminths

Infection by the larval forms of the nematode *A. cantonensis* can cause eosinophilic meningitis. *A. cantonensis* infection is fairly common in certain parts of the world (e.g., Thailand, Malaysia, Vietnam). Humans become infected when they ingest larvae in snails or slugs or by eating green leafy vegetables contaminated by these parasites. In the CNS, the larvae usually do not complete their life cycle and eventually die, surrounded by an eosinophilic infiltrate. Both peripheral and CSF eosinophilia are usually seen in these patients.

Gnathostoma spinigerum, a GI tract parasite of wild and domestic dogs and cats, may cause eosinophilic meningoencephalitis in humans. *G. spinigerum* is common in Southeast Asia, China, and Japan. Humans acquire the infection following the ingestion of undercooked infected fish and poultry. *Baylisascaris procyonis* is an ascarid parasite prevalent in the raccoon population in the United States and has emerged as a causative agent of human eosinophilic meningoencephalitis. Human infections occur following ingestion of food products contaminated with raccoon feces.

Neurocysticercosis is a major cause of brain lesions in certain parts of the world. It is caused by the larvae of the pig tapeworm *Taenia solium*. Humans become infected by ingestion of food or water contaminated with eggs of *T. solium*. Larvae released from the eggs migrate through the intestinal wall to the CNS and form cysts in the subarachnoid space. CSF may be normal or may show pleocytosis, with a predominance of neutrophils or eosinophils and decreased glucose level. The diagnosis is confirmed by radiographic studies and demonstration of cyst antigen in CSF or serum using an enzyme-linked immunoelectron transfer blot test.

Echinococcus granulosus, a tapeworm, causes the formation of hydatid cysts in humans. Humans are infected during contact with intermediate hosts for the parasite, such as sheep and dogs. Although the liver and lungs are the most commonly affected organs, the brain may be invaded by the parasite, resulting in seizures. Human visceral larva migrans results from ingestion of eggs of *Toxocara canis* or *Toxocara cati*. Although most of the larval stages are seen in the liver, some larvae reach the CNS and cause lesions in the brain.

Paragonimus westermani, the oriental lung fluke, is known to cause brain lesions. Human infection is confined to Japan, South Korea, Thailand, China, and the Philippines. Infection occurs by ingestion of raw or improperly cooked crustaceans. Neurologic symptoms, such as epilepsy and paralysis, are observed when the brain is infected. Serologic assays may be useful for the detection of *P. westermani*.

Neuroschistosomiasis can occur when schistosomes migrate to the brain or spinal cord and deposit eggs. Myelopathy is seen in infection with *Schistosoma mansoni* and *Schistosoma haematobium*; acute encephalitis has been reported with *Schistosoma japonicum* infections.

Case check 35.1

Laboratory findings in CSF can aid the diagnosis of meningitis. CSF characteristics differ, depending on the cause. In general, cell types, concentrations of glucose and protein, staining characteristics of the organism, culture, and other testing provide clues to the causative agent.

Meningoencephalitis and encephalitis

Patients with **meningoencephalitis** or **encephalitis** have involvement of the cerebral cortex. The diagnosis of encephalitis is usually inferred from the clinical presentation. Because of diffuse involvement of the cerebral cortex in patients with encephalitis, mental status changes and other focal or diffuse neurologic signs, such as seizures, are common. The most common causes of encephalitis are viruses, including herpesviruses, EVs, and arboviruses. Acute meningoencephalitis caused by paramyxoviruses, such as Nipah virus, have been reported in abattoir workers. Fruit bats are reservoirs of Nipah virus, and outbreaks caused by drinking raw date palm sap contaminated by bat saliva and excreta have been reported in Asia. In 2018, a Nipah virus outbreak occurred in India with 91% mortality, and the source was identified as the fruit bat in the index case. Nonviral causes include *L. monocytogenes*, *Rickettsia*, *Bartonella*, *Mycoplasma*, *B. burgdorferi*, *N. fowleri*, and *T. gondii*.

Clues to the cause of the encephalitis are sometimes available on physical examination, such as the rashes of Lyme borreliosis and Rocky Mountain spotted fever (RMSF). A history of tick bite may suggest a diagnosis of RMSF, Colorado tick fever, Lyme borreliosis, or ehrlichiosis. Herpes simplex encephalitis in adults may follow primary herpesvirus infection or result from reactivation of a previous herpesvirus infection. Neonatal herpes simplex meningoencephalitis usually reflects disseminated herpetic disease. Beyond the neonatal period, HSV encephalitis is usually caused by HSV-1. Patients usually have fever, altered sensorium, and focal neurologic signs consistent with temporal lobe involvement. Encephalitis from other herpesviruses is less common.

Arboviruses are RNA viruses that demonstrate strong tropism for the CNS. These viruses are transmitted to humans by mosquitoes, ticks, or sandflies. Important arboviruses in the Western Hemisphere include members of the genus *Alphavirus* (EEE, WEE, and Venezuelan equine encephalitis [VEE] viruses), *Flavivirus* (SLE virus), *Orthobunyavirus* (LAC virus), and *Coltivirus* (Colorado tick fever virus). The incidence of these infections can differ with the geographic region. EEE, the most severe arthropod-borne encephalitis in the United States, is typically a fulminant disease leading to coma and death in one third of cases and serious neurologic sequelae in another third. It is endemic along the entire East Coast of the United States. Infections are most common in young children and older adults.

WEE occurs predominantly in the Midwestern and Western United States. The clinical severity of WEE is intermediate, with a case fatality rate of 5%. VEE is endemic in Central America and Florida. WEE and VEE are difficult to distinguish from EEE on clinical grounds, and infants and young children are at greatest risk for infection. Fortunately, the risk of fatal encephalitis is much lower (about 10% in WEE and 0.6% in VEE).

Despite its name, SLE has been reported throughout the United States. Children and older adults experience more severe illness. It can present with confusion, fever, slow disease progression, lack of focal neurologic findings, generalized weakness, and tremors. The risk of fatal encephalitis is estimated at about 10%. LAC virus is the most commonly isolated member of the California serogroup of bunyaviruses. Encephalitis resulting from LAC virus usually occurs in

Ohio, Illinois, Wisconsin, and Minnesota. Children are most commonly afflicted. Infections with LAC virus and the other California serogroup viruses are relatively benign arboviral infections, with a mortality rate of less than 1%.

WNV is a mosquito-borne flavivirus that commonly causes a self-limiting febrile illness, often associated with a rash. In 1999, the virus was introduced into the United States and spread rapidly. Neurologic involvement includes aseptic meningitis, myelitis, and fatal encephalitis. The mortality rate is about 5%; death occurs mainly in older adult patients. Colorado tick fever virus belongs to the genus *Coltivirus* of the family Reoviridae. In addition to meningoencephalitis, Colorado tick fever virus shows a peculiar tropism for bone marrow, and infection is often accompanied by leukopenia and thrombocytopenia.

Rabies is a zoonosis caused by an RNA virus of the genus *Lyssavirus*. Infection occurs through bites by infected animals, such as skunks, raccoons, bats, foxes, and unimmunized domesticated animals, such as dogs and cats. Initial symptoms include fatigue, GI symptoms, and pain at the bite wound. Rabies can present as acute encephalitis indistinguishable from other viral encephalitides or with the classic syndrome of agitation, emotional lability, seizures, and hallucinations. Diagnosis is confirmed with demonstration of the rabies antigen (by immunofluorescence) in neck skin biopsies or by demonstration of the rabies antigen in the neurons of the brains of patients or infected animals.

More recently, associations between Zika virus (single-stranded RNA arbovirus member of the genus *Flavivirus*) and congenital CNS malformation have been reported. Cases of Zika virus associated with meningoencephalitis in adults were diagnosed by culture and PCR of CSF specimens.

Brain abscesses

Brain abscesses are circumscribed areas of tissue destruction containing organisms and inflammatory cells. A cerebral abscess begins as a focal area of acute inflammation, followed by the development of a necrotic center and the presence of macrophages and fibroblasts in the periphery. Eventually, there is a diminution in the necrotic center and formation of a collagenous capsule.

Most cerebral abscesses occur as a result of spread from a contiguous focus of infection in the middle ear, mastoid cells, or paranasal sinuses. Brain abscesses secondary to ear infections are usually localized in the temporal lobe or the cerebellum, and those attributable to spread from paranasal sinuses or from dental infections are seen in the frontal lobe. The second common mechanism for development of brain abscess is by hematogenous spread from a distant focus of infection, such as lung abscess, infective endocarditis, and intraabdominal infections.

Brain abscesses can also develop secondary to trauma with dural breach or following neurosurgery. In some patients, none of these pathogenic mechanisms are evident. The microorganism isolated from a brain abscess often depends on the predisposing condition. In patients with brain abscess secondary to ear or sinus infection, the common organisms include streptococci, *Bacteroides* spp., and *Prevotella* spp., whereas in patients with penetrating trauma or infective endocarditis, *S. aureus* is more likely to be identified. Neutropenic or transplant patients are more susceptible to developing infections

by fungi, such as *Aspergillus* or *Mucorales* spp.; patients with HIV are more likely to have infections by *T. gondii*, *Nocardia* spp., or *Mycobacterium* spp.

Bacterial pathogens

Streptococci are the most common organisms isolated from nontraumatic brain abscesses (Fig. 35.11). Streptococci, such as *Streptococcus anginosus*, *Streptococcus intermedius*, and *Streptococcus constellatus*, are isolated in 50% to 70% of cases. Mixed infections are seen in 30% to 40% of cases. Anaerobes commonly identified from brain abscess include *Bacteroides* spp. and *Prevotella* spp. Members of the order Enterobacterales, such as *E. coli*, *Proteus* spp., and *Enterobacter* spp., can sometimes cause brain abscesses. *Citrobacter diversus* meningitis is often associated with brain abscesses. In neonates, *Cronobacter sakazakii* has been reported to cause brain abscesses. *Actinomyces* and *Nocardia* spp. may also be isolated from patients with brain abscesses. Nocardial abscesses are more common in patients with HIV, organ transplant recipients, and those receiving corticosteroid therapy. It is important that samples obtained at the time of surgery be cultured under aerobic and anaerobic conditions.

Fungal pathogens

The increasing use of immunosuppressive drugs and broad-spectrum antimicrobials has contributed to the increasing incidence of fungal brain abscesses. In addition to *Candida* spp., *Aspergillus*, *Mucor*, *Rhizopus*, *Absidia*, and pigmented fungi (*Cladosporium trichoides*, *Xylohypha bantiana*, *Cladosporium bantianum*, *Cladophialophora bantiana*) are common fungi that can cause brain abscesses. Infection caused by *Candida* spp. is more common in patients with indwelling catheters, those receiving hyperalimentation, or those receiving long-term steroid therapy. *Aspergillus* infection and cerebral phaeohyphomycosis result from dissemination of the organism from a primary focus, usually the lung, or by direct extension, such as from paranasal sinuses. Presence of pigmented fungi in aspirates or tissue specimens is diagnostic for phaeohyphomycosis. Mucormycosis is more commonly seen in patients with diabetic ketoacidosis or hematologic malignancies or following transplants. The organism enters

Fig. 35.11 Direct smear of aspirated brain abscess contents. Clusters of intracellular gram-positive cocci in groups are consistent with microaerophilic streptococci (Gram stain, noncytacentrifuge preparation, $\times 1000$).

the CNS from paranasal sinuses by eroding the frontal bone to reach the CNS (rhinocerebral mucormycosis) or by hematogenous dissemination. Other fungi occasionally isolated from cerebral abscesses include *B. dermatitidis*, *C. neoformans*, *Coccidioides* spp., and *Pseudallescheria boydii*.

Case check 35.2

In CNS infections, such as brain abscesses, in which meningeal involvement is limited, CSF findings are not very characteristic and hence cannot be relied on to make a diagnosis. Accurate diagnosis of the causative agent may depend on tissue samples or aspirates or on serologic tests.

In the current coronavirus disease 2019 (COVID-19) pandemic caused by the severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), besides acute respiratory involvement, CNS manifestations (dizziness, headache, impaired consciousness, acute cerebrovascular disease, ataxia, epilepsy, nerve pain, and a reduction in taste, smell, and visual perception) were also reported. SARS-CoV-2, an RNA virus that belongs to the family Coronaviridae, was identified in neural and capillary endothelial cells in the frontal lobe of autopsied patients who died of COVID-19. The neurons and glial cells express the angiotensin-converting enzyme 2 (ACE2) receptor, the target for SARS-CoV-2. The neurologic manifestations may be caused by neuroinvasion or immune hyperactivation. Some patients develop the autoimmune Guillain-Barré syndrome. In general, patients presenting with symptoms of respiratory and/or CNS involvement caused by SARS-CoV-2 are diagnosed by a reverse-transcription polymerase chain reaction (RT-PCR) or antigen test using nasopharyngeal or nasal swabs.

Laboratory diagnosis

The diagnosis of CNS infections is based on examination of CSF, aspirates, and tissue samples. Blood cultures are often helpful in identifying the causative microorganism. A lumbar puncture is performed by inserting a sterile hollow needle into the spinal subarachnoid space in the lower (lumbar) back (Fig. 35.12). Lumbar puncture is often performed after computed tomography (CT) in patients with elevated intracranial pressure or focal neurologic lesions because of the risk of brain herniation. In patients with a brain abscess, aspirates and tissue samples are helpful because CSF may be normal.

Cerebrospinal fluid transport and analysis

CSF samples should be transported to the laboratory without delay and processed as soon as possible to prevent loss of viability of the causative agent. If delay cannot be avoided, CSF samples should be stored at room temperature until processed (within 24 hours). For viral testing, CSF samples may be stored at 2°C to 8°C in the short term (<48 hours) and at -70°C in the long term. When large volumes (>1 mL) of CSF sample are available, concentration by centrifugation increases the yield of microorganism for microscopic examination and culture. It is standard to obtain three to four tubes of CSF, each containing 1 or 2 mL of fluid. Cultures are

Fig. 35.12 Technique of lumbar puncture. The cerebrospinal fluid sample is obtained by inserting a long, sterile, hollow needle into the spinal subarachnoid space in the lumbar region.

performed on samples that have the least likelihood of contamination (second or third tube).

The CSF is analyzed for glucose and protein concentration, cell counts, and identification of the causative agent by Gram stain, culture, antigen detection, and PCR assay. Meningitis is suspected from the presenting clinical symptoms, findings on physical examination, and initial CSF studies, including visual inspection, chemical analysis, and cell counts. The characteristic CSF laboratory findings for various causative agents are compared in Table 35.1. The CSF white blood cell counts in neonates may not be helpful in the diagnosis of bacterial meningitis. Acid-fast staining and negative staining are useful in the diagnosis of tuberculous and cryptococcal meningitis, respectively. Cryptococcal antigen detection based on latex agglutination, enzyme immunoassay, and later flow methods are commercially available. Blood cultures are often positive in patients with bacterial meningitis if obtained before administration of antimicrobial therapy.

Culture

Isolation of fastidious organisms require special medium and incubation conditions. Anaerobic bacteria rarely cause meningitis but are commonly associated with brain abscesses. Transport media, such as the modified Stuart medium or Amies medium, are generally sufficient for transport of specimens. Sheep blood and chocolate agar plates incubated in 3% to 5% carbon dioxide (CO₂) are usually used for bacterial culture of CSF. Anaerobic cultures and prolonged incubation of broth media have been found to enhance the recovery of *Cutibacterium* spp. and *Propionibacterium* spp. from CSF cultures. When CSF samples are collected from shunts, broth media should also be inoculated. Blood cultures are not

Table 35.1 Characteristic cerebrospinal fluid findings in meningitis

Parameter	Organism					
	Bacterial	Fungal	Tuberculous	Syphilitic	Viral	Parasitic
Organisms seen in CSF	Usually	Less common	Rare	None	None	Rare
Cell count (leukocytes/ μ L)	100–100,000, neutrophils predominate	Normal– 500, lymphocytes predominate ^a	50–500, lymphocytes predominate ^b	100–750, lymphocytes predominate	Normal– 200, lymphocytes predominate ^c	Normal– 200, lymphocytes and/or eosinophils predominate
Protein ^d (mg/dL)	100–500	Normal–250	Normal–150	50–250	Frequently normal	Usually increased
Glucose ^e	Usually markedly decreased	Normal to decreased	Usually decreased	Normal	Normal	Normal to decreased
Additional findings	Bacterial antigen test	Calcofluor-concentrated specimen; latex agglutination (e.g., <i>Cryptococcus neoformans</i>)	PCR, auramine-rhodamine on concentrated specimen	Positive VDRL test result	Serology, PCR, culture, biopsy	Serology, biopsy

CSF, Cerebrospinal fluid; PCR, polymerase chain reaction; VDRL, Venereal Disease Research Laboratory.

NOTE: Critical values—any positive result of a microbiological test, such as direct stained smear, culture, polymerase chain reaction, or antigen testing, is considered critical and should be reported to the health care provider immediately.

^aMay have normal CSF cell count with *C. neoformans*. Eosinophils may predominate in *Coccidioides immitis* infection.

^bNeutrophils may predominate in early meningitis.

^cCSF cell count may be more than 1000 leukocytes per milliliter in lymphocytic choriomeningitis virus infection. Neutrophils may predominate in early meningitis.

^dCSF protein levels are age and laboratory dependent. A typical reference range for adults is 20 to 60 mg/dL.

^eCSF glucose levels are typically 60% of the blood glucose level. The reference range for the CSF/plasma ratio is 0.3 to 0.9.

useful in most CNS device infections but could be useful in ventriculoatrial shunt infections.

Molecular diagnostics

The BioFire FilmArray meningitis/encephalitis (ME) panel (biomérieux, Durham, NC) is a multiplexed in vitro diagnostic test that can be used to detect 14 pathogens (*E. coli* K1, *H. influenzae*, *L. monocytogenes*, *N. meningitidis*, *S. pneumoniae*, *S. agalactiae*, CMV, EV, HSV-1, HSV-2, HHV-6, PeV, VZV, and *C. neoformans*/*C. gattii*) simultaneously in CSF samples. The panel allows rapid detection (1 hour) with good sensitivity and specificity. A negative result in CSF samples collected from intrathecal devices should be interpreted with caution. Gram stain and culture will still need to be performed to identify pathogens not covered by the panel. Commercial assays such as the Xpert EV assay (Cepheid, Sunnyvale, CA), NucliSENS EasyQ Enterovirus assay (bioMérieux), and Simplexa HSV 1 & 2 Direct assay (DiaSorin, Cypress, CA) are some additional nucleic acid based assays that are cleared by the U.S. Food and Drug Administration (FDA) for the detection of viruses in CSF specimens. A list of FDA-cleared nucleic acid-based diagnostic tests can be found at <https://www.fda.gov/medical-devices/in-vitro-diagnostics/nucleic-acid-based-tests#microbial>.

Next-generation sequencing (NGS), still primarily a research method, can aid in the identification of viral agents of CNS infections, especially when traditional diagnostic methods fail. Novel cyclovirus, gemicircularvirus, astrovirus, and coronavirus OC43 have been identified in CSF specimens of patients with CNS infections of unknown cause by using NGS.

Bacterial infections

In acute bacterial meningitis, CSF is turbid or cloudy because protein levels are significantly increased. Glucose levels are low (<40% of the serum glucose concentration) in most patients with bacterial meningitis. The gold standard for diagnosis of bacterial meningitis is culture of CSF. Antimicrobial therapy reduces culture sensitivity. Staining techniques are rapid but less sensitive than culture. The sensitivity of Gram stain ranges from 40% to 90%, depending on whether the patient received antimicrobial therapy before lumbar puncture.

Latex agglutination tests for the detection of *H. influenzae* type b, *S. pneumoniae*, GBS, and *N. meningitidis* are available; however, these kits do not detect group B meningococci and coagulase-negative staphylococci. False-positive results can occur because of cross-reactivity with other bacterial species. False-negative results have been observed in specimens from pregnant women and infants. Routine use of antigen detection methods for diagnosis of bacterial meningitis is of limited value because the performance of the antigen test is similar to that of Gram stain, and a positive antigen test result usually does not alter the course of therapy. However, bacterial antigen testing may be beneficial in cases in which cultures are negative and clinical suspicion of bacterial meningitis is high or in cases of partially treated meningitis with sterile cultures. Multiplex PCR assays for the simultaneous detection of *N. meningitidis*, *H. influenzae*, and *S. pneumoniae* are available. These multiplex PCR assays are used in conjunction with traditional detection methods.

Viral infections

In viral infections, the number of lymphocytes in CSF is increased. The diagnosis of viral meningitis is based on detection of viral genome by PCR assay or detection of antigens by fluorescent antibody or enzyme immunoassay (EIA). The sensitivity of viral culture is only 14% to 24% compared with 88% to 94% with PCR, making PCR the method of choice for detection of viral causes of meningitis. The sensitivity and specificity of PCR assays can vary in relation to the virus being tested. Cell culture is recommended for EVs. However, due to cost, expertise required, and lengthy turn-around time, cell cultures are rarely performed in clinical microbiology laboratories. Recently, the GeneXpert EV assay (Cepheid), a real-time multiplex PCR assay for the detection of EV RNA in CSF, has become available. A positive result with the GeneXpert EV assay does not rule out other causes of meningitis. The results from this assay should be interpreted in conjunction with available clinical and laboratory information.

Real-time PCR assays are available for detection of PeV. For HSV, diagnosis includes detection of HSV DNA in CSF by PCR assay, growth of HSV on culture, antigen detection in brain biopsy samples, and demonstration of antibody in CSF and serum. Antigen and antibody assays have low sensitivity and are positive in the later stage of the disease. Although the PCR assay is highly sensitive, a false-negative result may be obtained in CSF samples obtained within the first 48 hours of illness. Repeated testing is helpful in such cases.

With infections caused by WNV, detection of IgM antibodies confirmed by the WNV plaque reduction neutralization antibody test is used for diagnosis, along with PCR and culture. The laboratory diagnosis of Japanese encephalitis virus is based on detection of viral RNA by PCR and virus-specific antibodies. Serum and CSF IgM antibody capture enzyme-linked immunosorbent assay (MAC-ELISA) has been widely accepted for the diagnosis of Japanese B encephalitis. However, the low specificity and cross-reactivity of the MAC ELISA has resulted in challenges in detection in areas in which Japanese encephalitis virus and other flaviviruses circulate simultaneously.

More recently, MassTag PCR, a multiplex PCR assay system with a library of primer sequences from a variety of pathogens that cause meningitis or encephalitis, has been developed. The tag from the amplified product is cleaved by ultraviolet light and is then analyzed by mass spectrophotometry. Chips that contain conserved sequences of viral genomes (DNA microarray) represent another new technology that is being developed for viral identification. In addition to the MassTag PCR and DNA microarrays, high-throughput DNA pyrosequencing using random primers has also been used to identify unknown viral pathogens.

Mycobacterial infections

Tuberculous meningitis is characterized by elevated lymphocyte count, elevated protein, and reduced glucose levels. The gold standard for diagnosis is identification of mycobacteria in the CSF by acid-fast staining and culture. Broth medium (e.g., Middlebrook 7H9, Dubos) and solid agar medium (e.g., Middlebrook 7H11, Löwenstein-Jensen) are used routinely to culture mycobacteria but require a long

incubation period (cultures held 6 weeks to 8 weeks). Use of the MGIT Mycobacterial Growth Indicator Tube (Becton Dickinson, Sparks, MD) or other automated systems, such as the MB/BacT (Organon Teknika, Durham, NC), ESP (Trek Diagnostic Systems, Westlake, OH), BACTEC9000 TB series, or BACTEC460 can increase recovery and reduce the time to detection of mycobacteria in CSF.

Direct staining is positive in 10% to 22% of cases, and cultures are positive in 38% to 88% of cases. The number of mycobacteria in CSF is usually small; therefore concentration of the CSF sample is useful in increasing recovery of the bacteria. Other techniques, such as the detection of mycobacterial antigen, antimycobacterial antibodies, or mycobacterial DNA by PCR assay, may be helpful. Commercial PCR assays are available for detection of *M. tuberculosis* in sputum and bronchial aspirates. These PCR assays have also been used for detection of mycobacteria in CSF; however, false-positive results do occur, and a negative test result does not exclude tuberculous meningitis. The PCR assays should be used in conjunction with culture.

Spirochetal infections

Lyme meningitis is also characterized by elevated lymphocyte, elevated protein, and reduced glucose levels. In symptomatic patients, diagnosis is made by using EIA or immunofluorescent assay followed by western immunoblot.

Fungal infections

Direct microscopic examination of Gram-stained or India ink-stained CSF samples, calcofluor-stained tissue samples, and culture are used to diagnose fungal causes of CNS infection. Concentration methods can increase the sensitivity of fungal staining and culture. Several media are available for fungal cultures of CSF or CNS tissue. All fungal cultures should be incubated for 4 to 6 weeks. Antigen detection by a latex agglutination test is useful in the case of infections caused by *C. neoformans* and *H. capsulatum*. The latex agglutination tests for *C. neoformans* show false-positive results with rheumatoid factor and in patients with infections caused by *Trichosporon* spp., *Stomatococcus mucilaginosus*, or *Capnocytophaga canimorsus*. False-negative results may be observed because of infection with a poorly encapsulated strain or low fungal burden. CSF and serum galactomanan levels are useful for the diagnosis of *Aspergillus* infections. Antibody detection using the complement fixation assay and immunodiffusion is useful for the diagnosis of *C. immitis*. PCR tests for routine detection of fungal DNA are not standardized.

Parasitic infections

The identification of parasitic causes of CNS infections is usually based on microscopic examination of Giemsa- or calcofluor-stained aspirate or biopsy samples (Fig. 35.13). Culture using agar with bacterial overlay is recommended for free-living amebae, such as *Naegleria* and *Acanthamoeba*, but not for *B. mandrillaris*. Serology and PCR testing are available for detection of *Toxoplasma*. Antibody detection by immunoblot is used as an adjunct serologic test for confirmation of radiologic diagnosis in patients with neurocysticercosis.

Fig. 35.13 This photomicrograph shows a magnified view of brain tissue, within which is a centrally located *Acanthamoeba* sp. cyst (hematoxylin and eosin stain, $\times 1000$). (Courtesy Dr. George Healy, Centers for Disease Control and Prevention, Atlanta, GA.)

Diagnosis of human trypanosomiasis is mainly via examination of unstained and Giemsa-stained blood smears, lymph node aspirates, bone marrow, or CSF for trypomastigotes. Other methods, such as the card agglutination trypanosomiasis test, various concentration techniques, and PCR, have been developed for the detection of trypanosomes but are mainly used as research tools. Concentration techniques using quantitative buffy coat analysis tubes increase detection sensitivity of the parasite. Hematocrit centrifugation and anion exchange column chromatography also increase the sensitivity of parasite detection. Examination of CSF processed by a double-centrifugation technique often reveals trypanosomes in patients in the late stage of the disease.

Case check 35.3

CSF samples should be transported to the laboratory without delay and processed as soon as possible to prevent loss of viability of the causative agent. In addition to routine laboratory testing, newer techniques for identification of viruses and other pathogens are becoming increasingly available. Rapid, accurate diagnosis of the causative agent is paramount in providing targeted therapy.

POINTS TO REMEMBER

- Host-related risk factors and pathogen-specific virulence factors are important in the pathogenesis of CNS infections.
- CSF characteristics, such as chemical and cellular features, may provide presumptive diagnostic clues about the cause of CNS infection.
- The age and immune status of the host will help determine likely causative pathogens.
- Virulence factors of disease-producing organisms enable them to evade host defense mechanisms and cause clinical infection.
- The prevalence of different viral pathogens can vary, depending on the season.
- The occurrence of opportunistic disease in patients with HIV infection is a function of underlying host immunodeficiency as well as pathogen virulence.
- Immunocompromised patients, including those who have undergone bone marrow or organ transplantation, are at increased risk for certain types of meningitis.

LEARNING ASSESSMENT QUESTIONS

- How is cerebrospinal fluid produced and distributed in the central nervous system?
- How would you characterize normal cerebrospinal fluid?
- Which common bacterial pathogens cause meningitis? Which host-related and virulence-related factors are associated with each pathogen?
- How would you compare the physical, chemical, and cellular findings in cerebrospinal fluid analysis in bacterial, fungal, tuberculous, and viral meningitis?
- Which fungal species are typically associated with intracerebral abscesses?
- Which fungal species are associated with meningitis?
- Why should you examine CSF specimens as soon as they are received?
- How would you initially evaluate the CSF sample?
- Which types of culture media should be used to recover bacterial pathogens?
- Which rapid and other ancillary methods are useful for evaluating CNS infections?
- An 18-year-old recruit is examined at the military health clinic. He is disoriented with a fever, intense headache, stiff neck, vomiting, and sensitivity to light. His roommates at the barracks say that he has been sick for about 2 days and that his condition worsened over the past 3 hours. The patient's serum electrolytes are normal, but the white blood cell count is 12,000 cells/ μ L. Which test should the health care provider order next?
 - Urinalysis and urine culture
 - Stool Gram stain and culture
 - Cerebrospinal fluid Gram stain and culture
 - Sputum Gram stain and culture
- Cerebrospinal fluid specimens should be analyzed for infectious agents as quickly as possible. How should a specimen collected in the hospital be transported to the laboratory?
 - Wet ice
 - Dry ice
 - At room temperature
 - Transport medium
- What are the most common bacteria isolated from nontraumatic brain abscesses?
 - Streptococci
 - Staphylococcus aureus*
 - Bacteroides* spp.
 - Escherichia coli*
- The direct Gram-stained smear of cerebrospinal fluid taken from a 4-week-old infant shows gram-positive cocci. Which of the following organisms would be highly suspected?
 - Escherichia coli*
 - Streptococcus pneumoniae*
 - Listeria monocytogenes*
 - Streptococcus agalactiae*
- A hunter is bitten by a raccoon. He washes the wound with soap and water and then puts a dressing on it. A few days

later, he notices that the wound is swollen and feels painful. He begins to experience seizures and hallucinations. Which condition corresponds with the hunter's symptoms and history?

- West Nile virus encephalitis
- Rabies
- St. Louis encephalitis (SLE)
- Colorado tick fever

Systemic inflammatory response syndrome (SIRS)

Transient bacteremia

Viremia

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Differentiate bacteremia from septicemia.
2. Classify each type of bacteremia including when each condition occurs.
3. Discuss the epidemiology and pathogenesis of bacteremia.
4. Associate specific organisms with each type of bacteremia.
5. Explain the pathophysiology of sepsis and septic shock.

Case in point

A 4-year-old male patient with acute lymphocytic leukemia was undergoing induction chemotherapy administered via an

indwelling Hickman catheter and was hospitalized because of fever and granulocytopenia. His admission white blood cell (WBC) and platelet counts were $6 \times 10^9/\text{L}$ (reference range 4.5 to $11 \times 10^9/\text{L}$) and $55 \times 10^9/\text{L}$ (reference range 150 to $400 \times 10^9/\text{L}$), respectively, and his oral temperature was 103°F (39.4°C), reference range 95.9°F (35.5°C) to 99.5°F (37.5°C). Two sets of blood cultures were drawn before antimicrobial agents were administered. He was immediately given ceftazidime and vancomycin. All four blood culture bottles yielded gram-positive cocci in clusters after 24 hours of incubation. The isolate was identified as a coagulase-negative *Staphylococcus* sp. Removal and culture of the Hickman catheter and culture tip yielded the same organism with the same susceptibility pattern as that isolated from blood. Therapy was switched to more appropriate agents.

Issues to consider

After reading the patient's case history, consider:

- Conditions that predispose patients to bacteremic episodes
- Consequences of bacteremia caused by gram-negative and gram-positive organisms
- Source site where the organisms originate
- Appropriate blood culture method for isolation and recovery of the infecting agent

Bacteremia is the presence of viable bacteria in the bloodstream. Although bacteremia may be a transient, self-limiting phenomenon without clinical consequences, it frequently reflects the presence of serious infection. Life-threatening infections caused by bacteremia are a concern in patients who are immunocompromised because of drug or chemotherapeutic intervention or as the result of preexisting disease and subsequent immunosuppression. Bacteremia is often associated with hospitalization, insertion of foreign bodies, such as catheters into blood vessels, and other types of procedures.

This chapter begins with general concepts pertinent to bacteremic infections including definitions of conditions relating to bacteremia and how each condition is manifested, and then discusses the following:

- The epidemiology of risk factors for and pathogenesis of bacteremia
- Infections associated with bacteremia
- Diagnostic laboratory procedures
- Treatment modalities

General concepts related to bacteremic infections

Definitions

The presence of viable bacteria in the blood, as determined by their growth in a blood culture, is known as **bacteremia**. It is a laboratory finding that may or may not indicate infection. Blood cultures may become positive because of contamination during phlebotomy, leading to false-positive results, a phenomenon termed **pseudobacteremia**. Skin commensals, such as coagulase-negative staphylococci (CoNS), are common contaminants. Pseudobacteremia is not an indication of infection and does not require therapy. However, growth of

CoNS or other skin microbiota from a blood culture does not always represent pseudobacteremia; it may indicate true bacteremia, depending on the clinical situation.

Even when growth of an organism from a blood culture reflects a true-positive result, bacteremia may not be associated with any physical signs or symptoms of severe infection, a condition known as **occult (unsuspected) bacteremia**. Occult bacteremia frequently occurs in children younger than 2 years of age and is most often caused by *Streptococcus pneumoniae*. Because of the lack of clinical evidence for serious infection in such patients, the diagnosis of bacteremia may be overlooked, with potentially catastrophic consequences if treatment is delayed.

Usually, however, bacteremia that reflects true infection results in systemic physiologic responses that indicate the presence of a serious infection. In the past, the term **septicemia** was used to indicate bacteremia plus a clinical presentation of physical signs and symptoms of bacterial invasion and toxin production. The term *septicemia* is still used clinically and in the collection of epidemiologic data on causes of death. Because of its imprecision in defining a disease state, however, it is not suitable for categorizing all patients who have bacteremia-related infections or for designing clinical trials.

To facilitate the study of the pathogenesis and treatment of the consequences of severe infections, including those associated with bacteremia, an international consensus conference of the American College of Chest Physicians and the Society of Critical Care Medicine devised standardized definitions of the response to infection, shown in [Table 36.1](#). **Systemic inflammatory response syndrome (SIRS)** comprises a spectrum of increasingly severe conditions ranging from noninfectious inflammatory response to **sepsis** (infection with a systemic inflammatory response) to severe sepsis (sepsis accompanied by organ dysfunction, hypotension, or tissue hypoperfusion) to **septic shock** (sepsis accompanied by refractory hypotension). As might be expected, the risk of death progressively increases as patients move along this continuum. Although bacteremia may result in sepsis, severe

Table 36.1 Definition of terms related to severe infection

Term	Definition
Systemic inflammatory response syndrome	Systemic response to a variety of clinical insults. Criteria include at least two of the following: • Temperature $>38^\circ\text{C}$ or $<36^\circ\text{C}$ • Heart rate >90 beats/min • Respiratory rate >20 breaths/min, or partial pressure of carbon dioxide (PaCO_2) <32 mm Hg • White blood cell count $>12 \times 10^9/\text{L}$ or $<4 \times 10^9/\text{L}$, or $>10\%$ band forms
Sepsis	Infection with systemic inflammatory response
Hypotension	Systolic blood pressure <90 mm Hg, mean arterial pressure <70 mm Hg, or reduction >40 mm Hg from baseline
Severe sepsis	Sepsis associated with organ dysfunction, hypoperfusion, or hypotension
Septic shock	Sepsis with hypotension despite adequate fluid resuscitation and requiring pressor therapy, along with perfusion abnormalities

sepsis, or septic shock, these responses are not automatically associated with bacteremia. For example, blood culture results may be negative in more than 70% of patients with sepsis despite clear clinical signs of infection.

Classification of bacteremia

Site of origin

Bacteremia may be classified by its site of origin. **Primary bacteremia** occurs when the bacteria are present in an endovascular source such as an infected cardiac valve or an infected intravenous (IV) catheter, whereas **secondary bacteremia** occurs when the bacteria come from an infected extravascular source, such as lungs in patients with pneumonia. A case in which the source of bacteremia remains undefined is termed *bacteremia of unknown origin*. Classification in this manner has important clinical consequences because it determines the appropriate therapy and prognosis. For example, a secondary bacteremia from an infected focus, such as an abscess, may require surgical therapy to remove the abscess or source of infection, in addition to antimicrobials to eliminate the infection. Bacteremia of unknown origin generally has a poorer prognosis than primary or secondary bacteremia.

Causative agent

Bacteremia may also be categorized by the general class of microorganism or specific pathogen that has invaded the bloodstream. Gram-positive bacteremia is caused by such organisms as *S. pneumoniae*, *Staphylococcus aureus*, or *Enterococcus faecium*, whereas gram-negative bacteremia is caused by such organisms as *Escherichia coli* or *Pseudomonas aeruginosa*. Anaerobic bacteremia is caused by such organisms as *Bacteroides fragilis*, whereas **polymicrobial bacteremia** is caused by a mixture of organisms. General classification of bacteremia in this fashion can provide initial clues to the underlying source of a bacteremia and guide therapy, even before organisms have been identified. For example, CoNS bacteremia in a hospitalized patient is frequently caused by infection of an indwelling vascular device, whereas polymicrobial bacteremia with a mixture of enterococci and gram-negative organisms is frequently caused by invasion of the bloodstream by gastrointestinal (GI) microbiota from bowel perforation.

Place of acquisition

Bacteremia can also be categorized by its place of acquisition. **Community-acquired bacteremia**, as the term suggests, occurs in individuals living in the general community, whereas **healthcare-associated bacteremia** occurs in patients who are hospitalized or living in a nursing home or other health care facility. To avoid misclassification of bacteremia that began at the time of hospital admission as healthcare-associated, when it is, in fact, community acquired, a healthcare-associated infection is conventionally defined as any bloodstream infection occurring more than 72 hours after hospital admission.

Certain bacteremias are more often community acquired. For example, more than 90% of cases of *S. pneumoniae* bacteremia are acquired in the community. Others, such as those caused by *P. aeruginosa* or *Enterococcus* spp., are more likely to be healthcare-associated. The place of acquisition may thus be extremely significant in guiding initial therapy. For example,

healthcare-associated bacteremia is more likely to be caused by drug-resistant organisms that express β -lactamases or other resistance factors that inactivate first-line antimicrobial agents, although this distinction is currently blurred in the case of hospital-acquired and community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA).

Duration

Bacteremia may also be classified by the duration of a bacteremic episode. Bacteremic episodes may be *transient*, *intermittent*, or *continuous*. The frequency, time, and number of blood cultures to be collected may depend on the type of bacteremic episode that the patient is experiencing. **Transient bacteremia** usually occurs after a procedural manipulation of a specific body site colonized by indigenous microbiota, causing the organisms to enter the vascular system. Such sites include the mouth and the GI and urogenital tracts. Transient bacteremia may appear for a brief period following a dental, colonoscopic, or cystoscopic procedure. The organisms involved are normally rapidly cleared by the host immune defense, so their presence is rarely symptomatic.

Intermittent bacteremia can occur because of the presence of abscesses somewhere in the body or as a clinical manifestation of certain types of infections, such as meningococcemia, gonococcemia, or pneumonia. In intermittent bacteremia, organisms are periodically released from the primary site of infection into blood. **Continuous bacteremia** occurs when the organisms are coming from an intravascular source and are consistently present in the bloodstream. Infective endocarditis is the most common clinical manifestation associated with continuous bacteremia, although other endovascular sources, such as infected intravascular catheters or septic thrombi, can also result in continuous bacteremia. Microbial biofilms (see [Chapter 31](#)) on foreign body implants and in tissue can contribute to continuous bacteremia by the periodic release of planktonic microorganisms.

Epidemiology

Incidence and mortality

Brill reported the first case of bacteremia (caused by *Bacillus pyocyaneus*, now *P. aeruginosa*) in 1899. Ten years later, fewer than 40 cases had been reported worldwide, with fewer than 30 additional cases in the following 15 years. Bacteremia currently occurs in more than 250,000 hospitalized patients in the United States, but not all of these cases result in septicemia. Between 1950 and 2003, however, the mortality rate caused by septicemia increased almost 40-fold. Septicemia (as defined by the *International Classification of Diseases* [ICD]-10) was the 11th leading cause of death overall in the United States in 2019 (1.42 % of total deaths) based on data from the Centers for Disease Control and Prevention (CDC). In 2019, CDC reported bacterial sepsis as the seventh leading cause of death among newborns, with 16.1 deaths/100,000 live births.

Documented bacteremia is a fundamental determinant of septicemia, which often leads to shock and death. The incidence of septic shock in patients with bacteremia ranges from 10% to 30%, depending on the pathogen, source of bacteremia, presence of immunosuppression, and presence or absence of comorbid conditions, but once present, septic

shock is associated with a mortality rate of 30% to greater than 50%. According to the CDC, mortality rates in patients with bacteremia and fungemia currently remain as high as 12% and as high as 25% for candidemia specifically. Patients with severe sepsis and septic shock who have three or more failing organs have a mortality rate of 70%. Factors associated with an unfavorable outcome in bacteremia include the following: age older than 70 years; polymicrobial bacteremia; presence of malignancy, acquired immunodeficiency syndrome (AIDS), or renal failure; origin of the bacteremia in the respiratory tract or bowel; unknown origin of bacteremia; and delayed or inappropriate antimicrobial therapy.

Risk factors

The increased incidence of bacteremia in the United States during the past 30 years is likely a result of the following factors, some of which have changed dramatically over this period:

- Decreased immunocompetency of selected patient populations
- Increased use of invasive procedures
- Age of the patient
- Antimicrobial resistance
- Diagnostic criteria and coding practices
- Injection drug use
- Nasal colonization (in the case of *S. aureus* bacteremia)

Decreased immunocompetency of selected patient populations

Bacteremias are more frequent among persons with *neoplasia* (abnormal growth of new cells that may be benign or malignant), especially those with hematologic malignancies, those receiving immunosuppressive chemotherapy, and those undergoing bone marrow transplantations. This is caused, in part, by a decrease in the levels of circulating neutrophils in such patients as well as disruption in the GI mucosa attributable to chemotherapy, allowing invasion of normal microbiota into the bloodstream. Persons with other chronic underlying diseases (e.g., diabetes, cirrhosis) and those receiving immunosuppressive therapy (e.g., those receiving glucocorticoids for rheumatoid arthritis, stem cell or solid organ transplant recipients) are also at increased risk for bacteremia. Infection with human immunodeficiency virus (HIV) predisposes patients to increased risk of bacteremias because of the immunosuppression caused by the virus.

Increased use of invasive procedures

The increased use of indwelling devices, respirators, and invasive diagnostic procedures is a common cause of bacteremia and actually the leading cause of healthcare-associated bacteremia. The widespread use of semi-permanent vascular catheters (to administer chemotherapy to patients with cancer or to provide vascular access for hemodialysis in patients with end-stage renal disease) increases the risk of bacteremia by breaking the normal integrity of the skin and permitting colonization of a foreign body in direct contact with the bloodstream. According to the National Healthcare

Safety Network, more than 30,000 bacteremias (central line-associated bloodstream infections [CLABSI]) occur annually in the United States because of infected central line venous catheters, with a mortality rate of 12% to 25%. Indwelling urethral catheters, suprapubic catheters, and IV pyelography also predispose patients to catheter infections by penetrating otherwise sterile areas, encouraging colonization with bacteria from surrounding tissue. Surgery involving the urinary, GI, and biliary tracts may also result in bacteremia because of the disruption of mucosal barriers that normally function to block the spread of resident microbiota.

Age of the patient

Bacteremias are more prevalent in people at the extremes of age, with infants, young children, and adults older than 55 years of age being most susceptible. Both infants and older adults have decreased immune system function compared with people 5 to 55 years of age. In very young patients a competent immune response has not yet fully developed, and in older adults there is a general decrease in immunocompetency with age. The presence of comorbid conditions, such as diabetes, hypertension, chronic obstructive pulmonary disease, and congestive heart failure, in older adults and neoplastic disorders, HIV infection, and low and very low birth weights in neonates and infants significantly increases the incidence of bacteremia in these groups.

Case check 36.1

The patient in the Case in Point had several risk factors for developing bacteremia: he was immunocompromised (leukemic), was hospitalized, and had an indwelling catheter. Other risk factors for bacteremia include very young age, old age, and trauma. The increased number of persons with these risk factors partly explains the recent increase in bacteremias noted.

Antimicrobial resistance

The indiscriminate administration of broad-spectrum antimicrobials reduces susceptible normal microbiota and favors colonization and invasion by resistant bacteria. Data from the SENTRY Antimicrobial Surveillance Program (2012–2017) revealed that, on average, 37% of *S. aureus* isolates from bloodstream infections in the United States were resistant to methicillin (oxacillin), 26.4% of *Enterococcus* blood isolates were resistant to vancomycin, 15.8% of Enterobacterales blood isolates were multidrug resistant, 21.5% of *Klebsiella* spp. blood isolates were extended-spectrum β -lactamase (ESBL) producers, and 15.4% of *P. aeruginosa* blood isolates were multidrug resistant. These percentages vary widely from region to region and are higher in patients with healthcare-associated infections based on the WHO Global Antimicrobial Resistance and Use Surveillance System [GLASS] report, 2021.

Although the rates of *S. aureus* bloodstream infections occurring in hospitalized patients decreased by almost 50% from 1997 to 2007 and 54% between 2005 and 2011, the percentage of *S. aureus* isolates that were MRSA dramatically increased; therefore numbers of MRSA blood infections remained fairly constant. There were approximately 120,000 MRSA bloodstream infections documented in the United

States in 2017, resulting in 20,000 deaths. According to the CDC, the rate has decreased slowly, but community-acquired methicillin-sensitive *S. aureus* (MSSA) bacteremia has increased to 3.9% annually. An increasing population of antimicrobial-resistant organisms results in bacteremias that are harder to treat, leading to increased morbidity and mortality.

Diagnostic criteria and coding practices

The factors described have been shown to lead to an actual increase in the incidence of bacteremia. There may be some artificial increase in the incidence of bacteremia because of variations in the diagnostic criteria for bacteremia and how bacteremias are coded in the patient record. It is difficult to compare rates from one study to another because of these changes over time (e.g., pre-consensus conference to post-consensus conference changes) and changes from one health care institution to another and one health care provider to another. In addition, there are multiple ICD codes that may apply to bacteremia and/or fungemia; for example, bacteremia, septicemia, disseminated fungal infection, disseminated candidal infection, and disseminated fungal endocarditis are all assigned separate ICD-10 codes. Several of these codes overlap and could potentially apply to the same infection. Investigators in different studies may consider some or all of these when evaluating rates of bacteremia and fungemia. Finally, each revision of the ICD is slightly different. Since 2004, hospitals have been using the 10th revision, second edition, of the ICD.

Causes

Over the past 25 years, the pattern of organisms responsible for bacteremia has shifted. In the 1960s and 1970s, gram-negative organisms, such as *E. coli* and *P. aeruginosa*, predominated in prospective studies of bacteremia. In the 1980s and 1990s, the pattern shifted such that most bacteremias in the United States were caused by gram-positive organisms, such as *S. aureus*, CoNS, and *Enterococcus* spp., although gram-negative organisms still represented a large proportion of cases. A SENTRY 20-year trend report (2019) states that bacteremias caused by gram-negative organisms are again increasing, with high rates of gram-negative infections occurring in infants (up to 42%). Fungal invasion of the bloodstream (**fungemia**) caused by such organisms as *Candida albicans* and *Candida auris* has become increasingly important.

In recent data from the CDC (2021), the most common causative bloodstream pathogens, in descending order, from catheter-related bloodstream infections (CRBSIs) are CoNS, enterococci, *S. aureus* (both MSSA and MRSA), aerobic gram-negative bacilli, and *C. albicans*. Table 36.2 shows the frequencies of bacteremia caused by different organisms in a 2004 hospital-based prospective survey of healthcare-associated bacteremias (most commonly catheter related). Recent shifts in the microbiology are likely a result of risk factors discussed earlier: widespread use of indwelling vascular catheters (readily colonized by CoNS); immunosuppressive cancer chemotherapy, which renders patients susceptible to infection by CoNS and other commensals that normally do not cause disease in immunocompetent individuals; and increasing antibiotic drug resistance in gram-negative rods.

Table 36.2 Most common organisms associated with hospital-acquired bacteremias

Organism	Percentage of bacteremias (N = 20,978)
Coagulase-negative staphylococci	31.3
<i>Staphylococcus aureus</i>	20.2
<i>Enterococcus</i> spp.	9.4
<i>Candida albicans</i>	9.0
<i>Escherichia coli</i>	5.6

Data from Wisplinghoff H., et al. (2004). Hospital-acquired bloodstream infections in US hospitals: analysis of 24,179 cases from a prospective nationwide surveillance study. *Clinical Infectious Diseases: an Official Publication of the Infectious Diseases Society of America*, 39, 309.

In addition to the shift in organisms responsible for bacteremia, the susceptibility patterns of pathogens causing bacteremia have also changed. Bacteremia caused by MRSA, a rare entity in the 1970s, now accounts for more than 40% of all hospitalizations for *S. aureus* bacteremia, and the incidence of bacteremia caused by vancomycin-resistant enterococci (VRE) has also increased. In addition, gram-negative organisms expressing ESBLs and carbapenem-resistant Enterobacterales (CRE) have become more prevalent, complicating the therapy of patients with bacteremia resulting from these organisms. These shifts are thought to be caused by the increasing use (and misuse) of broad-spectrum antimicrobials, resulting in selection of multidrug-resistant pathogens.

The microbiology of bacteremia is also marked by an increasing incidence of polymicrobial bacteremia. In the 1930s, almost every case of bacteremia involved a single organism. By the early 1990s, 10% of bacteremias involved more than one organism. Polymicrobial bacteremia is generally associated with a higher mortality than monomicrobial bacteremia. The predisposing factors in polymicrobial bacteremia include IV drug use, burns, and GI tract sources. Especially at risk are immunocompromised patients, particularly those with alcoholism, granulocytopenia, extensive burns, diabetes mellitus, and chronic renal failure, and patients with vascular insufficiency attributable to ischemia. *B. fragilis* often has been associated with polymicrobial infections. Given the resistance of *B. fragilis* to many antimicrobials, its involvement in bacteremia carries an increased risk for death.

Finally, some organisms have become less prevalent causes of bacteremia because of immunization practices that have decreased the risk of infection. For example, the incidence of infection with *Haemophilus influenzae* type b (Hib), formerly a major cause of bacteremia and sepsis in children, decreased by more than 95% after introduction of the conjugate Hib vaccine in the 1980s. Similarly, implementation of the *S. pneumoniae* vaccine in the 1970s resulted in an 84% reduction of bacteremia caused by *S. pneumoniae* as well. Interestingly, according to one study, there has been a 67%

reduction in bacteremia in general in 3- to 36-month-old children. *S. pneumoniae* now accounts for <2% of bacteremias (SENTRY 20-year trends, 2019).

Pathogenesis

The pathogenesis of bacteremia depends, in part, on the infecting pathogen, portal of initial entry, and immune status of the patient. In general, however, bacteremia occurs because of disruption of normal skin or mucosal barriers, leading to bacterial invasion of the bloodstream. Such disruption may occur because of trauma, burns, or ischemia giving rise to breaks in the skin that allow access to the microvasculature; an antecedent viral infection that disrupts the epithelial lining (e.g., influenza virus infection involving the upper respiratory tract) and allows resident biota to invade the bloodstream via capillaries; or iatrogenic disruptions, such as surgery, instrumentation, or placement of an indwelling device. Alternatively, a focal bacterial infection (e.g., bacterial pneumonia) may lead to bacteremia via local inflammation, edema, and tissue destruction that disrupts nearby vascular structures and allows bloodstream invasion.

Once bacteremia occurs, the patient's immune system attempts to control infection via antibodies that opsonize organisms and activate complement-mediated killing and by phagocytosis. In addition, filtering mechanisms in the lymphatics and large vascular beds in the liver and spleen may sequester organisms and facilitate their destruction by phagocytic cells. If, however, these defenses are unsuccessful, two major complications may ensue—metastatic infection and septic shock. Invasion of the bloodstream may result in spread of organisms throughout the body, causing seeding of multiple sites and leading to widely disseminated infection. For example, bacteremia caused by *S. pneumoniae* can lead to infection of the meninges, resulting in pneumococcal meningitis, a catastrophic infection with a mortality rate as high as 25%, even with optimal treatment. Other infections associated with a period of bacteremia as part of the disease process include salmonellosis, infective endocarditis, and acute hematogenous osteomyelitis. *S. aureus* is particularly likely to cause metastatic infection or abscess formation as a consequence of bacteremia; *S. aureus* bacteremia may lead to endocarditis, osteomyelitis, septic arthritis, hepatic abscess, or pyomyositis. Sepsis and septic shock are also potential consequences of bacteremia.

Although gram-negative bacteremias were once thought to be more likely to cause septic shock than bacteremias caused by gram-positive organisms, the risk of sepsis, severe sepsis, septic shock, and death is now known to be similar between these two classes of bacteremia. In both cases, a bacterial membrane component (lipopolysaccharide, also known as *endotoxin*, in gram-negative organisms, lipoteichoic acid and peptidoglycan in gram-positive organisms) interacts with macrophages and causes the release of tumor necrosis factor, interleukin (IL)-1, IL-6, and other proinflammatory cytokines, increasing endothelial activation, vascular permeability, blood flow, and recruitment of neutrophils. These responses are directed at controlling infection and are normally counterregulated by anti-inflammatory mediators to prevent a destructive systemic inflammatory reaction. In sepsis and septic shock, however, an imbalance in regulation leads to an

unopposed proinflammatory state, leading to microvascular abnormalities and endothelial injury; in turn, these derangements lead to decreased tissue perfusion, complement activation, and **disseminated intravascular coagulation (DIC)**, which cause multiorgan dysfunction, eventually leading to septic shock and death.

Clinical aspects of bacteremia

Syndromes associated with bacteremia

Numerous sources can give rise to bacteremia. The most common sites associated with bacteremia and sepsis are infected intravascular catheters, urinary tract, lung, and abdomen.

Catheter-related bloodstream infections

Intravascular catheters have become indispensable for modern medical and surgical therapy. Most of these are temporary catheters placed in peripheral veins and are intended for short-term use in the administration of medications and fluids. Semi-permanent catheters (Hickman, Broviac, Quinton, or Tenckhoff catheters, so named after their developers) are placed in central veins and remain in place for weeks or months to administer chemotherapy and/or parenteral nutrition to patients with cancer or to perform hemodialysis in patients with end-stage renal disease. Still other catheters are placed in arteries or, via central veins, the pulmonary artery or right-sided chambers of the heart, where they may be left for days for hemodynamic monitoring.

As useful as these devices are, they are exquisitely vulnerable to colonization and biofilm formation by gram-positive organisms, such as CoNS, *S. aureus*, and *Enterococcus*, which are often found on the surface of the patient's skin, with subsequent spread to the bloodstream to cause bacteremia. Frequently the strains causing CRBSIs are resistant to multiple antimicrobials. Substantial progress has been made in the past 20 years, however, in reducing these infections. CDC data revealed more than 30,000 cases of documented CRBSI in the United States in 2018 in hospital patients, a 58% reduction since 2001. Most of these infections are caused by CoNS. Production of a polysaccharide biofilm by CoNS is one mechanism that has been associated with CRBSI. The biofilm may serve as a ligand during initial surface adhesion and colonization, or it may be produced after the organism has established a focal presence by adhering to the surface. The biofilm also protects the organism from host defenses by inhibiting phagocytosis, chemotaxis, and oxidative metabolism and by suppressing the lymphoproliferative response. It may also significantly increase the concentrations of antimicrobials required to inhibit the growth of CoNS attached to the catheter.

Although CoNS are of relatively low virulence, bacteremias caused by these organisms in patients with compromised immune systems (e.g., patients with cancer becoming neutropenic through chemotherapy) are associated with mortality rates of 13% to 18%. Bacteremias caused by *S. aureus* are associated with higher mortality rates, partly because of the virulence of this organism and the ease with which it adheres to native cardiac valves and causes endocarditis. Occasionally,

fluids administered via these catheters become contaminated via a break in infusion lines, causing bacteremia. Organisms associated with such infusion-associated bacteremias are typically gram-negative organisms, such as *P. aeruginosa* and *Enterobacter cloacae*. Bloodstream infections caused by nontuberculous mycobacteria associated with intravascular catheters are rapidly emerging among immunosuppressed hosts, most notably *Mycobacterium avium* complex in HIV-positive individuals.

Case check 36.2

The Case in Point is a classic example of a CRBSI with CoNS, weakly virulent organisms that can be pathogenic in a high-risk patient. Bacterial contamination via the catheter likely introduced the organism into the bloodstream. This was demonstrated by recovery of the same organism with the same susceptibility from culture of the catheter and the blood. Removal of the catheter was the clinically appropriate action.

Urinary tract infections

Infection of the upper urinary tract (acute pyelonephritis) leads to bacteremia in as many as 40% of affected patients. *E. coli* is the predominant cause of bacteremia in this setting. These infections are most common in older adult patients.

Pneumonias

Common organisms in cases of pneumonia that produce a concurrent bacteremia include *S. pneumoniae*, *S. aureus*, *P. aeruginosa*, *Klebsiella* spp., and *Enterobacter* spp. Of patients with pneumococcal pneumonia, 25% to 30% will have positive blood cultures; the case fatality rate is 5% to 7%, and likely much higher in older adult patients.

Intraabdominal infections

Primary peritonitis, which frequently occurs in patients with cirrhosis, is associated with bacteremia in 75% of cases involving aerobic bacteria. Common pathogens include *E. coli*, *K. pneumoniae*, and enterococci. Secondary peritonitis arising from perforation of the GI tract may give rise to intraabdominal abscesses, resulting in intermittent bacteremia caused by *E. coli*, anaerobes, and enterococci. In some cases, intraabdominal abscesses may be caused by seeding of the liver or spleen by a transient bacteremia arising from outside the abdomen, most often caused by *S. aureus*.

Skin infections

Cellulitis caused by *S. aureus*, *Streptococcus pyogenes*, or *Streptococcus agalactiae* can lead to bacteremia. Skin breakdown in bedridden patients (bed sores or decubitus ulcers) or peripheral vascular disease from diabetes is a common cause of infected skin ulcers, which can provide a portal of entry for bacterial invasion of the bloodstream, often resulting in polymicrobial bacteremia. Commonly reported offending organisms include *Proteus mirabilis*, *E. coli*, *S. aureus*, *B. fragilis*, *Pseudomonas* spp., *Clostridium* spp., and

Peptostreptococcus. Surgical treatment of abscesses and wounds can result in bacteremia. Patients with severe burns who become bacteremic most often grow gram-negative organisms, especially *P. aeruginosa* and *Klebsiella pneumoniae*. IV drug use, under unsterile conditions, can also result in bacteremia by introducing skin microbiota, environmental organisms, or mouth biota (from licking needles) into the bloodstream.

Infective endocarditis

Transient bacteremia (from dental procedures or a superficial skin infection) can seed cardiac valves with bacteria. These organisms multiply within a dense vegetation composed of bacteria and fibrin, protected from killing by neutrophils, and give rise to a continuous bacteremia that can then seed other organs. Continued growth can lead to valvular damage and congestive heart failure. Organisms associated with acute, sudden-onset endocarditis include virulent bacteria, such as *S. aureus*, enterococci, and *S. pneumoniae*, whereas the more slowly progressing subacute endocarditis is commonly caused by less virulent bacteria, such as viridans streptococci; nutritionally variant streptococci, including *Abiotrophia* and *Granulicatella*; and CoNS (particularly in prosthetic heart valves).

Musculoskeletal infections

Acute osteomyelitis is often associated with transient bacteremia caused by *S. aureus*; frequently the portal of entry is an otherwise unnoticed minor skin infection. The organisms seed end loop capillaries in bone, where blood flow is slow, and begin to multiply, causing destruction of bone and giving rise to intermittent bacteremia in about 50% of cases. Prosthetic joints, particularly those implanted in the hip, can be hematogenously seeded by such organisms as *S. aureus* and CoNS and then give rise to bacteremia. Occasionally, prosthetic joint infections are caused by intraoperative contamination, although this risk has decreased considerably because of the use of perioperative prophylaxis and ultra-clean operating rooms. Prosthetic joint infection with virulent organisms such as *S. aureus* or group A β -hemolytic streptococci can lead to florid sepsis and death. Bacteremia caused by *S. aureus* or *Neisseria gonorrhoeae* can result in seeding of joints and cause acute septic arthritis, an infectious disease emergency that requires prompt drainage of pus from the joint and aggressive antimicrobial therapy.

Central nervous system infections

Acute bacterial meningitis is generally the result of transient bacteremia caused by *S. pneumoniae* or *Neisseria meningitidis*. These organisms may colonize the nasopharynx in normal individuals and occasionally invade the bloodstream to cause disease. Occasionally, meningitis is caused by bacteremia resulting from sinusitis or otitis caused by *S. pneumoniae*.

Signs and symptoms

The classic signs and symptoms of bacteremia include abrupt onset of shaking chills, fever, or hypothermia. About 14% of patients with bacteremia will have hypotension, and about

40% of patients experience prostration and diaphoresis (profuse sweating). Tachypnea (abnormal rapid breathing) is an early sign of bacteremia, and adult respiratory distress syndrome occurs in 18% of patients with culture-positive septic shock. Other symptoms may include delirium, stupor, or agitation (evidence of decreased central nervous system perfusion), along with nausea and vomiting. As many as 38% of patients with bacteremia and sepsis will have acute renal failure, with oliguria or anuria. Ecthyma gangrenosum, a central necrotic area surrounded by an erythematous base, is typically associated with *Pseudomonas* bacteremia. The failure of the body to mount an elevated temperature is associated with increased mortality in newborns and older adults. Clinical conditions with altered laboratory values that may be indicative of bacteremia include the following:

- Thrombocytopenia
- Leukocytosis or leukopenia
- Lactic acidosis
- Hypoglycemia or hyperglycemia
- Abnormal liver function test results (especially hyperbilirubinemia)
- Coagulopathy, including DIC
- Elevations in C-reactive protein (CRP), haptoglobin, and fibrinogen levels

Laboratory diagnosis

Specimen collection

Because of the potential of a serious negative outcome of a septicemia or bacteremia, a blood culture is one of the most important cultures to obtain rapid accurate results. As such, a positive blood culture is a critical value (Box 36.1). Critical values are laboratory test results that are outside of the reference range and indicate a potentially fatal outcome. The health care provider must be notified immediately of all critical values to provide immediate treatment. In the case of a positive blood culture, the Gram stain result should be called to the health care provider immediately.

BOX 36.1 Critical values

The following must be communicated immediately to the health care provider:

- Positive Gram-stained smear result from bottle for bacterial or yeast blood culture
- Positive acid-fast smear result from bottle for mycobacterial blood culture

Some facilities consider the following critical values that must be communicated (but others do not):

- Positive direct coagulase from blood culture bottle result (indicates presence of *Staphylococcus aureus*)
- Positive Quellung capsule staining result (presumptive *S. pneumoniae*)
- Positive modified Kinyoun stained smear result (presumptive *Nocardia* sp.)
- Positive peptide nucleic acid fluorescence in situ hybridization result for yeasts, *Enterococcus* sp., or *S. aureus*
- Definitive identification of *Mycobacterium tuberculosis* from blood culture

It is important to remember that even though antiseptic technique is used in the collection of blood, somewhere between 1% and 3% of blood cultures become contaminated with such organisms as CoNS, *Corynebacterium* spp., *Bacillus* spp. (not *B. anthracis*), α -hemolytic streptococci, and *Cutibacterium acnes*, which are ordinarily skin colonizers, resulting in pseudobacteremia. However, in some patients, including those undergoing cancer chemotherapy, such organisms can represent true pathogens, making it essential to distinguish between blood culture results that reflect true bacteremia and those that represent pseudobacteremia.

Therefore it is most important to prepare the skin properly before venipuncture for blood culture. Palpation for the vein can be checked with a gloved finger. Cleansing the skin with 70% to 95% ethanol or isopropyl alcohol followed by 2% chlorhexidine (preferred) or 2% tincture of iodine, scrubbed in a concentric fashion around the venipuncture site is recommended. For decontamination to be effective, the antiseptic should be left on the skin for at least 30 seconds. After the venipuncture, the disinfecting agent should be removed with an alcohol pad. Because of systemic absorption and their effect on thyroid function, iodinated antiseptics should not be used on low-birth-weight infants. Similarly, in infants younger than 2 months of age, chlorhexidine should not be used; instead, alcohol swabs should be used.

When blood is collected for culture, it is critical that the blood not be allowed to clot. The formation of a clot will trap the bacteria and reduce the ability to detect them. Thus blood should be inoculated directly into blood culture bottles or, if necessary, into a tube containing anticoagulants. Tubes containing heparin, ethylenediaminetetraacetic acid (EDTA), and sodium citrate have been shown to inhibit the growth of many different organisms and should not be used. Tubes containing 0.025% to 0.050% **sodium polyanethol sulfonate (SPS)** are better tubes to use for collecting blood for culture, although SPS can inhibit a few organisms as well, notably *Peptostreptococcus anaerobius* and some strains of *Neisseria* spp. and *Streptobacillus moniliformis*. Intermediate collection tubes are therefore not recommended.

Blood for blood culture should be obtained by venipuncture and not from indwelling IV or intraarterial lines. There is more risk of isolating skin microbiota from indwelling lines rather than via venipuncture. If blood is collected from an indwelling line, a second sample collected via venipuncture should be cultured for comparison. For patients who have IV lines through which they are getting fluids and/or medications, blood must be drawn below the line because blood drawn above the line will be diluted with the fluid being transfused. The best practice, however, is not to draw blood from the extremity that has an IV line but to perform venipuncture on an extremity that does not have an indwelling line.

Determining the volume, frequency, and number of blood cultures

Density of bacteremia in adults versus neonates

Bacteremia may involve a large number of microorganisms in the blood; however, more commonly, only a relatively small number of bacteria per unit volume of blood (as low as one bacterium per milliliter) is seen in patients with clinically significant bacteremia. The detection methods commonly

used in most laboratories produce positive results in adult patients with bacteremia if organisms are present in the range of 10 to 15 bacteria per milliliter of blood; however, there are circumstances in which patients have fewer than this number.

Studies that have examined the relationship between the volume of blood collected and rate of positivity have demonstrated that as the volume of blood cultured is increased from 2 to 20 mL per culture, the yield of positive culture results increases from 30% to 50%. One study clearly demonstrated the advantage of culturing 10 mL of blood per blood culture bottle compared with 5 mL of blood per bottle, finding that 7.2% more cases of bacteremia were detected in the bottle inoculated with 10 mL of blood and that the organisms were detected sooner than in the bottles inoculated with only 5 mL of blood. Unfortunately, a number of studies have found that it is common practice to inoculate blood culture bottles with less than the recommended volumes of blood.

If inoculating more blood into the blood culture bottle increases the sensitivity and rate of detection, why not inoculate even more blood than recommended into each bottle? Taking excessive amounts of blood from a patient can induce anemia in the patient, and according to at least one study, inoculating more than 10 mL per bottle did not increase the rate of positivity and decreased it instead.

Blood naturally contains many inhibitors of bacterial growth, from complement and lysozyme to WBCs. When more blood is inoculated into the blood culture bottle, the amount of inhibitors in the bottle is also increased, resulting in fewer bacteremic episodes detected in culture. In addition, although blood should be collected before antimicrobial agents are given, it is likely that many patients from whom blood is drawn are already receiving antimicrobial treatment that also inhibits the growth of bacteria in blood culture bottles. Thus blood and the inhibitors present in blood need to be diluted by the blood culture medium. The optimal ratio of blood to culture medium is about 1:5 to 1:10. The dilution aids in negating the bactericidal effect of normal serum. In cases in which a 1:5 dilution cannot be achieved, 0.025% to 0.050% SPS can be added to the bottle; this serves to inhibit complement, coagulation, and phagocytosis within the bottle.

In newborns, sepsis tends to be more severe because of their immature immune defense mechanisms and generally higher numbers of microorganisms per milliliter of blood. It is not uncommon, however, to see low-level bacteremia in children as seen in adults. Because newborns and children have a smaller volume of total blood, it is not safe to take as much blood from a newborn or child as that which can be taken from an adult. As a rule, about 4% of an adult patient's total blood volume can be taken safely for culture, but there is controversy over appropriate volumes to collect from infants and young children. In 2007, the Clinical and Laboratory Standards Institute (CLSI) recommended that no more than 1% of total blood volume be drawn for culture in infants and young children. Age-volume protocols used in the past are not recommended; these have become highly inaccurate in the present-day population. A protocol published by the American Society for Microbiology (ASM) in 2005 used the relationship between weight and blood volume to determine how much blood can be drawn for culture in this age group, assuming that similarly to adults, up to 4% of blood volume can be safely obtained.

In this scheme, 2 mL of blood can be safely collected from a newborn weighing less than 1 kg (<2.2 lb), 4 mL total from a newborn weighing up to 2 kg (up to 4.4 lb), 6 mL total from a child weighing up to 12.7 kg (27 lb), and 10 mL total from a child weighing up to 36.3 kg (up to 80 lb). A child who weighs more than 36.3 kg (>80 lb) can have as much blood drawn as an adult (20 to 30 mL). Because less blood is typically drawn from newborns and children compared with adults, most commercial blood culture systems have pediatric bottles that contain less blood culture medium into which less blood is inoculated. The ratio of blood to broth is kept at 1:5 to 1:10; some pediatric bottles may be supplemented with X and V factors to enhance the recovery of *H. influenzae*, which is more likely (or was more likely before implementation of the Hib vaccine) to be isolated from children than from adults.

Frequency of bacteremic episodes versus time and frequency of collection

The frequency of bacteremic episodes is another factor to consider when determining the timing and frequency of blood collection for culture. Because bacteremia can be transient, intermittent, or continuous with respect to the presence of microorganisms in the peripheral circulation, collection of samples may depend on the type of bacteremia suspected.

In patients with transient bacteremia, organisms are immediately cleared from the peripheral system by the reticuloendothelial system, and their presence is rarely symptomatic. In suspected cases of intermittent bacteremia, patients may present clinical symptoms, especially fever, but they may not occur until after bacteria have been cleared from the bloodstream. Because these symptoms serve as the signal to obtain blood cultures, bacteremia may go undetected because of delays in obtaining blood cultures relative to the time of peak concentration of circulating bacteria. Therefore it is recommended that blood culture specimens be collected before an anticipated temperature rise to ensure maximum recovery. However, in some patients, such as those with infective endocarditis who have continuous bacteremia, the organisms are constantly released into the bloodstream and hence are likely to be isolated whenever the blood culture specimen is taken.

Rationale for multiple blood collections

Although a single set of blood culture bottles may yield the causative agent, two, three, and even four sets of blood cultures are recommended. A set consists of one bottle for recovery of aerobic organisms and a second bottle for recovery of anaerobic organisms.

There are several reasons for drawing multiple blood cultures. One study revealed that about 80% of bacteremia are discovered in the first set of blood culture specimens taken, 90% are detected if two sets of specimens are taken, and as many as 99% are detected if a third set is taken. Other studies have duplicated these results and found, in addition, that it is not so much the number of blood cultures collected that improves the detection of bacteremia but the total volume of blood that is cultured, as noted. In the past, guidelines for the collection of blood for culture stated that multiple blood cultures should be submitted when blood is collected from multiple different venipuncture sites, with 30 to 60 minutes between draws.

Although it is best to collect blood when the patient's temperature spikes or before it does, because this is when more

organisms are present in the blood, not all patients have fever when microorganisms are in the blood, and it is almost impossible to predict when fever will occur. Because organisms can be present in the blood transiently or intermittently, and there is no way to know when the organisms are present, collecting blood at the optimal time for organism recovery can be a hit-or-miss procedure. Arbitrary timing of 30- to 60-minute intervals between draws has shown no significant differences in positivity rates; therefore blood culture sets may be obtained simultaneously or consecutively as long as they are from separate venipunctures. The exception is in suspected infective endocarditis, for which 30- to 60-minute intervals are recommended to document continuous bacteremia.

According to several recent studies determining best practices for timing and blood volume collection that yield the highest percentage of positive cultures, at least 60 mL of blood should be collected in a 24-hour period, with 10 mL of blood inoculated into each bottle; three sets of two bottles each will satisfy the volume requirement and will likely result in the detection of bacteremia, if present.

Another reason for inoculating multiple bottles with blood collected from multiple separate venipunctures is to aid in the determination of whether an isolated organism is a true pathogen or a contaminant. The collection of one single sample should be strongly discouraged because the volume of blood cultured is not sufficient for detecting some infections, as noted. In addition, for example, the significance of the isolation of CoNS or other skin microbiota from one culture is hard to interpret. Their presence could represent true infection, or it could be a result of contamination. It is not until there have been repeated isolations of the same organism from multiple cultures collected from separate venipunctures that the significance can be determined.

Most blood culture systems have separate bottles for the isolation of aerobic and anaerobic bacteria, as noted earlier. This practice has been questioned because the incidence of bacteremia caused by obligate anaerobes was found to be decreasing in some studies. Some investigators have recommended that two aerobic bottles be inoculated instead to maintain the necessary volume of blood that should be collected and increase the ability to detect the aerobic and facultative anaerobes that are more commonly isolated. Additional studies into the incidence of anaerobic bacteremia, however, have shown that anaerobes are not infrequent isolates, but that their presence is difficult to predict based on analysis of clinical predictors, and that antimicrobial resistance is increasing among anaerobes, making these infections important to detect. Thus, the inoculation of separate aerobic and anaerobic bottles remains the standard recommended procedure for blood cultures, although this can differ among institutions, depending on their isolation rates of anaerobes. If the recommended amount of blood for a set of bottles is not obtained, the aerobic bottle should be inoculated first with the appropriate volume of blood; the remaining blood can be inoculated into the anaerobic bottle, rather than splitting the volume between the two bottles.

Multiple blood cultures are recommended to document bacteremia, but there is a limit to the number that should be collected. Repeated blood cultures or daily collections of blood for culture are not necessary. If at least 40 mL of blood has been cultured, and antimicrobial therapy has begun, it is best to wait for the results of the initial sets of cultures

before collecting more blood. Most organisms grow within 3 to 5 days in the continuous-monitoring systems used in most laboratories, so it is best to wait at least 3 days before collecting additional blood for culture. If no organisms grow in the blood cultures, it is more reasonable to consider other potential causes of patient symptoms, rather than culturing more blood.

Case check 36.3

The patient in the Case in Point had two sets of blood cultures drawn, a total of four bottles, which was appropriate and clinically helpful. The more sets drawn, the more likely it is that an infective agent will be recovered. The organism isolated was a CoNS, which is frequently a contaminant, but because all four bottles were positive, it was easier to determine that this was a true pathogen rather than a contaminant. If only one set had been drawn or only one bottle had been positive, it would have been difficult to make any conclusions.

Blood culture methods

Culture media used in conventional broth systems

As noted, a blood culture set typically includes a bottle designed for recovery of aerobic microorganisms and another bottle for recovery of anaerobic microorganisms. The typical aerobic culture bottle contains a nutritionally enriched medium, such as soybean casein digest broth, peptone broth, tryptic or trypticase soy broth, brain-heart infusion broth, Brucella broth, or Columbia broth base. Although anaerobic broth may contain the same types of basic media as the aerobic culture systems, 0.5% cysteine may be added to permit the growth of certain thiol-requiring organisms, and the media may be prereduced to decrease the oxidation-reduction potential to help support the growth of anaerobes. Newer anaerobic broth media, such as the BD BACTEC FX (BD Diagnostic Systems, Sparks, MD), contain blood-lysing agents that reduce the time to detection of anaerobes by lysing red blood cells (RBCs), which provides added nutrients, and WBCs, which releases phagocytized organisms. Unvented blood culture bottles generally can be used to support anaerobic organisms.

Neutralization of inhibitors

In specimens from patients receiving β -lactam antimicrobial agents, penicillinase may be added to the medium to inactivate these agents, although this is rarely done today. More commonly, commercially available automated blood culture systems generally contain antimicrobial neutralization substances such as resin or charcoal that absorb or inactivate any antimicrobial agent present in the patient's blood. The recovery of bacteria and yeasts increases with the incorporation of these neutralizing agents into the culture medium.

Anticoagulants and other additives

SPS, one of the commonly used additives, performs the following functions:

- Anticoagulation (effective at a 0.03% concentration)
- Neutralization of the bactericidal activity (i.e., complement and lysozyme) of human serum

- Prevention of phagocytosis
- Inactivation of certain antimicrobial agents (e.g., streptomycin, kanamycin, gentamicin, polymyxin B)

Despite its usefulness in blood culture media, SPS inhibits the growth of certain organisms, notably *P. anaerobius*, *N. gonorrhoeae*, *N. meningitidis*, and *Gardnerella vaginalis*. If these organisms are suspected, 1.2% gelatin added to the blood culture bottle may help neutralize the inhibitory effect of SPS.

Other anticoagulants and supplements are available for use in blood culture systems, but they are not better than SPS. Sodium amylosulfate (SAS) is a structural relative of SPS that is less effective in neutralizing serum bactericidal activity and is inhibitory to *K. pneumoniae*. Sodium citrate (0.5% to 1.0%), an anticoagulant, is inhibitory to some gram-positive cocci. Sucrose (10% to 30%) is sometimes used as an osmotic stabilizer. Sucrose is especially helpful in dealing with bacteria that have undergone cell wall damage, and the resultant hypertonicity counteracts the normal bactericidal effect of blood. Other supplements, such as the anticoagulants ammonium-potassium or sodium oxalate and EDTA, are not recommended.

Incubation conditions

Continuous-monitoring blood culture instruments, as described later, include an incubator. An incubator used to incubate agar media plates can be used to incubate blood culture media of manual systems. In automated systems, blood culture bottles are typically incubated at $35^{\circ} \pm 2^{\circ}\text{C}$ for 5 days and may be held for 7 days for manual systems. During incubation of the bottles in a continuous-monitoring blood culture system, the aerobic bottles and, in some systems, the anaerobic bottles as well may be agitated during incubation. The agitation can take the form of a rocking motion, BacT/ALERT (bioMérieux, Durham, NC) and BACTEC (BD Diagnostic Systems), or a rotary motion with the formation of a vortex, VersaTREK (TREK Diagnostic Systems, Independence, OH). Agitation of the bottles increases oxygenation of the aerobic broth, enhancing the detection of microorganisms in the bottles and decreasing the time to detect growth. The head space of the bottles contains ambient air, sometimes with increased concentration of carbon dioxide (CO_2) in the aerobic bottles. The anaerobic bottles will have an increased concentration of nitrogen (N_2) and CO_2 replacing all the oxygen (O_2) in the bottle to facilitate isolation of obligate anaerobes.

Blood culture systems

Manual systems

Although only three manual blood culture systems are currently marketed and rarely used in the United States, they are important to understand for clinical microbiologists in areas that do not have resources for or access to automated systems. They are easy to use, inexpensive, and generally adequate for the detection of common bacteria and fungi. A broth-slide system (Septi-Chek, BD Diagnostic Systems) was designed from the original biphasic (solid agar and broth combination) blood culture medium called the *Castañeda culture bottle*. Septi-Chek consists of a slide paddle containing chocolate (CHOC), MacConkey (MAC), and malt extract agars (selective for yeast and fungi) attached to the top of a standard

broth bottle. Once these bottles have been inoculated, they should be tipped daily or at least twice weekly to bathe the slide paddle with the broth culture medium, thereby allowing frequent blind subcultures without the use of needles and syringes. Bacterial growth appears as small discrete colonies or as a confluent growth on the slide paddle. Most organisms will grow within 48 hours of inoculation, but the bottles are incubated for 7 days before they are discarded and reported as negative. This system has the advantage of providing more rapid recovery of facultative anaerobic bacteria and isolated colonies for identification and susceptibility testing. There are disadvantages, however, including a slightly higher cost of materials and contamination rate, and they are labor-intensive. An additional unvented bottle is still required for adequate isolation of anaerobes.

The Oxoid Signal system (Thermo Fisher Scientific, Waltham, MA) is a manual blood culture system in which blood is inoculated into a bottle containing a liquid medium that will support the growth of aerobes, anaerobes, and microaerophiles. A clear plastic signal device is then attached to the top of the bottle. The Oxoid Signal device has a long needle that extends down into the bottle below the level of the liquid. When microorganisms grow in the bottle, they generate CO_2 , which accumulates in the head space of the bottle. The increase of gas in the atmosphere of the bottle increases pressure on the liquid, forcing it up through the needle and into the clear plastic signal device. The presence of fluid in the signal device can be seen by the microbiologist during daily inspection of the bottles and indicates bacterial growth. The fluid from the signal device can then be removed for Gram staining and plating. The inoculated Oxoid bottles are incubated at $35^{\circ} \pm 2^{\circ}\text{C}$, agitated on a shaker, for the first 24 hours. Bottles are held for a total of 7 days, with a terminal blind subculture performed and examined before the culture is reported as negative.

The lysis centrifugation method (Isolator/Isostat; Wampole Laboratories, Inverness Medical Professional Diagnostics, Princeton, NJ) has been shown to provide optimal recovery of unusual fastidious bacteria such as *Bartonella*, yeasts, filamentous and dimorphic fungi, and mycobacteria that are causing systemic infections. This method produces a concentrated sample of blood for direct inoculation onto appropriate solid agar media, as opposed to the two systems described earlier, in which blood is inoculated and incubated in a broth medium. The Isolator tube contains a mixture of saponin, propylene glycol, SPS, and EDTA. This mixture causes lysis of WBCs and RBCs, releases intracellular organisms, prevents clotting, and neutralizes complement. Microorganisms are concentrated through high-speed centrifugation (3000g for 30 minutes). The sediment containing the organisms is directly inoculated onto solid culture media that includes fungal and mycobacterial media.

Examination of blood culture bottles in a manual system

Blood culture bottles are examined macroscopically with transmitted and reflected light for evidence of turbidity, hemolysis, gas production, or bacterial colonies in or on the blood layer. If visible growth is observed, 0.25 mL of blood should be aspirated with a sterile needle and syringe. A

smear is prepared for Gram stain and then plated to a solid medium. In addition to examination of the blood culture fluid for evidence of microbial growth, the Septi-Chek paddle is examined daily for the presence of colonies; the Oxoid bottle Signal device is examined daily for the presence of fluid, indicating microbial growth in the medium. Any finding of microbial growth should be reported immediately to a health care provider.

Continuous-monitoring blood culture systems

The BACTEC system (BACTEC 460; BD Diagnostic Systems) was the first automated growth detection system for blood cultures that detected the growth of microorganisms using radiolabeled carbon (^{14}C) glucose in the broth medium. When the organism in the blood culture bottle used the ^{14}C -labeled substrate, $^{14}\text{CO}_2$ was released. The instrument monitored $^{14}\text{CO}_2$ production by aspirating gas into an ionization chamber by using sterile needles injected into the bottle. In the ionization chamber, the amount of $^{14}\text{CO}_2$ produced was measured as a growth index and compared with an established threshold level. If the patient's blood culture showed a growth index that exceeded the threshold level, the instrument sent a signal indicating that the bottle was positive. The automated radiometric blood culture system had the advantage of early detection of bacterial growth, especially of slow-growing bacterial species (e.g., *Mycobacterium tuberculosis*). The disadvantages included the high initial cost of the instrument, high contamination rate (the result of inadequate needle sterilization

between bottles), and hazards and expense associated with radioisotope disposal. The development of subsequent automated blood culture instruments kept the detection of CO_2 as an indication of microbial growth.

BACTEC 9000 series and BD FX

To eliminate radioactive isotopes as a growth detection mechanism, BD Diagnostic Systems introduced the BACTEC 9000 series. Three models are currently available—the 9240 (holds 240 bottles per module), the 9120 (holds 120 bottles per module), and the 9050 (holds 50 bottles per module). The FX holds 400 bottles per module. These are noninvasive, continuous-monitoring blood culture instruments that use fluorescence to detect CO_2 . When a bottle is placed into the instrument, a baseline reading of the sensor is taken; this reading is used as a reference for subsequent readings. When microorganisms grow in the bottle, the CO_2 that they produce is detected by a gas-permeable sensor on the bottom of each vial (see later).

CO_2 produced by an organism diffuses into the sensor, generating hydrogen ions. The increase in hydrogen ion concentration increases the fluorescence output of the sensor. Using photodetectors, the instrument measures the amount of fluorescence every 10 minutes, which corresponds to the amount of CO_2 produced by the microorganism. A computer program then interprets these data using several algorithms to determine when to flag a bottle as positive. The instrument alerts the microbiologist to the presence of a positive vial by displaying a message on the computer monitor and with an audible alarm. Figure 36.1 shows the BACTEC 9000 schematic.

Fig. 36.1 BACTEC 9000 schematic. (Courtesy Becton, Dickinson, Sparks, Md.)

VersaTREK

The former Difco ESP system has been replaced by the VersaTREK automated detection system. VersaTREK differs from the other continuous-monitoring systems in that it detects the consumption or production of multiple gases (CO₂, hydrogen [H₂], and O₂) by organisms growing in the culture medium. These gases are detected by monitoring changes in head space pressure. The advantages to this system include the detection of different gases that may be produced or consumed by an organism present in the bottle, not just production of CO₂, and earlier detection of growth by detecting the consumption of gas as organisms enter the log phase of growth, before they start to produce CO₂. An internal computer algorithm monitors the changes in pressure, plots the pressure against time to derive a growth curve, and determines when to flag the bottle as positive.

BacT/ALERT 3D system

A fully automated, nonradiometric blood culture system, the BacT/ALERT 3D system, consists of aerobic and anaerobic bottles with pH-sensitive membranes placed in the bottom of the bottles. Microbial growth causes a release of CO₂, which changes the pH in the sensor, as indicated by a change in color from gray to yellow. The color change is measured by reflected light. The instrument measures CO₂ production colorimetrically without entering the bottles. An advantage of this system is that the changes in the color of the sensor can be detected and verified, if necessary. Another advantage of this system is that in 2003, bioMérieux released gas-impermeable plastic blood culture bottles that are safer and lighter than traditional glass bottles and do not interfere with microorganism growth or metabolism.

Recovery of other types of organisms from blood

The most common organisms isolated in one study of health-care-associated bacteremia are listed in [Table 36.2](#). All organisms listed in this table are easily recovered by traditional routine blood culture methods. Other organisms, however, can be found in blood that require special conditions to be detected. Communication with the health care provider is critical in deciding when and what extraordinary procedures should be performed.

Francisella tularensis

Francisella tularensis, the causative agent of tularemia, is best recovered from a liquid blood culture medium to which L-cysteine and glucose have been added.

Leptospira spp.

Leptospira spp. are best recovered early in the disease before onset of symptoms. Therefore blood should be collected as soon as this infection is suspected, during the first week of disease, with 1 to 3 drops of freshly drawn blood placed in 5 mL of Fletcher medium. Alternatively, 0.1 mL of heparinized blood can be inoculated onto Ellinghausen-McCullough-Johnson-Harris medium. Cultures are incubated at 30°C for 1 to 3 months in the dark and examined weekly by using dark-field microscopy. Other methods of diagnosis (polymerase

chain reaction [PCR], serology) are recommended because they are often more sensitive and timelier for detection of this organism, and treatment can be initiated more quickly, resulting in more favorable patient outcomes.

Brucella spp.

Brucella spp. require extended incubation times. When *Brucella* is suspected, conventional, manual blood culture medium (Ruiz Castañeda) should be held for up to 6 weeks at 35° ± 2°C and terminally subcultured. Automated blood culture systems show higher yields and faster recovery, but bottles should be held for 10 to 14 days. The manual lysis centrifugation system (Isolator) shows increased yields but carries the risk of exposure during manipulation and plating. Handling of suspected *Brucella* specimens and cultures should be done using special safety precautions, at least BSL 2 and preferably BSL 3 conditions, and sent to state health laboratories for confirmation and speciation. *Brucella* is usually diagnosed by serologic assays, but culture is considered the gold standard.

Nutritionally variant streptococci

The nutritionally variant streptococci (NVS) include *Abiotrophia* and *Granulicatella*. These streptococci are adequately recovered by using standard broth culture bottles because of the vitamin B₆ present in human blood. However, a pyridoxal-containing blood agar medium, addition of a pyridoxal disk to a blood agar subculture plate, or staphylococci streak is necessary for subculture to recover this group of streptococci on standard sheep blood agar, though they grow well on CHOC agar. The staphylococci streak test is performed with a confluent growth of the test organism on a blood agar plate. A single line of *S. aureus* is streaked across the middle of the plate. Following 24 hours of incubation, the plate is observed for satellitism—tiny colonies growing near the *S. aureus*.

Campylobacter spp.

Campylobacter lari, *Campylobacter fetus*, and *Campylobacter upsaliensis* can be isolated from blood. Although *Campylobacter jejuni* may grow in blood culture bottles, subcultures will show no growth unless the broth is subcultured onto selective media or enriched media, such as CHOC agar, and incubated in a microaerophilic environment at 42°C for 48 hours. A clue that the bottle contains *Campylobacter* will be the presence of curved gram-negative rods in the blood culture broth. These organisms are often difficult to find in the Gram-stained smears of the blood culture bottle; counterstaining with the darker pink basic fuchsin instead of safranin may help with visualization. An alternative stain, such as acridine orange (AO), can also be used.

Coxiella burnetii

Coxiella burnetii is the most common fastidious bacterium reported in the literature as causing endocarditis. Because *Coxiella* is an obligate intracellular pathogen, it cannot be isolated with typical blood culturing systems. It can be isolated in cell culture, but this should not be attempted unless the laboratory is equipped to handle dangerous pathogens. Instead, *Coxiella* is better detected by serology.

Bartonella spp.

Bartonella spp. are best isolated using lysis centrifugation and plating the concentrated blood onto freshly prepared media containing 5% horse or rabbit blood. Plates must be incubated for at least 3 weeks in a humid atmosphere containing elevated CO₂ levels at 35° to 37°C. Because the isolation of *Bartonella* spp. is difficult, serology and molecular methods of detection are preferred.

HACEK group of gram-negative bacilli

These bacteria (see [Chapter 18](#)) are known causes of endocarditis and will grow in blood culture bottles within 5 days. Extended incubation times and a terminal subculture are recommended only if blood cultures are negative at 5 days and there is a high clinical index of suspicion for these organisms.

Mycobacteria from blood

Using special media, *Mycobacterium* spp. can be detected with the automated blood culture systems discussed earlier. Medium in the bottles contains a lysing agent and enrichment (Middlebrook based) designed for long incubation periods, up to 6 weeks. The Isolator system can also be used to culture blood for mycobacteria. Plated selective media are held for 6 to 8 weeks before mycobacteria can be ruled out.

Fungemia

The presence of fungi in the blood is termed **fungemia**. *Candida* spp. are isolated almost as frequently as are gram-negative bacilli from blood in some institutions. Yeasts grow in the continuous-monitoring blood culture systems. The best way to recover filamentous or dimorphic fungi in blood, however, is to use the Isolator system with fungal agar plates, which are usually held for 4 weeks. Yeasts and dimorphic fungi are the most common fungi isolated from blood.

Viremia

Viremia, the presence of viruses in blood, is determined by serology or molecular-based detection systems. Viruses that can be detected from blood include cytomegalovirus, Epstein-Barr virus, adenoviruses, and enteroviruses.

Contamination in blood cultures

A contamination rate of 1% to 3%, although not desirable, can be expected, with CoNS, *Micrococcus* spp., diphtheroids, and *C. acnes* as common contaminants. Any organism cultured from two or more blood culture bottles, however, should not be assumed to be a contaminant. All of the organisms mentioned can also be responsible for bacterial endocarditis. Contamination rates should be monitored; if they increase above 3%, an examination of phlebotomy practices should be performed along with reeducation of phlebotomists and nurses with regard to appropriate methods for collecting blood for culture.

Other sources of contamination causing pseudobacteremia include IV catheters as well as various skin disinfectant solutions. Benzalkonium chloride has been demonstrated to be occasionally contaminated with *Burkholderia cepacia* and

Enterobacter spp. Alcohol or iodine as a skin disinfectant has been preferred. However, contamination of certain iodine solutions, such as povidone-iodine, with *B. cepacia* has also been reported. Contamination with *Serratia marcescens* and *Moraxella* spp. has been reported in some evacuated blood collection tubes.

In the past, contamination was more clear-cut. The media and volume of blood used now are more sensitive and grow more contaminants. It can be difficult to determine the difference between a true pathogen and contamination. As the volume of blood increases, the number of positive blood culture results increases. Microbiologists cannot make this determination (true pathogen or contaminant) in the laboratory; health care provider input and patient history are needed. Criteria that can be used to determine whether an isolate from a blood culture is a pathogen or contaminant include the following:

- Identity of the microorganism isolated. *S. aureus*, *E. coli*, and other members of the Enterobacterales; *S. pneumoniae*; *P. aeruginosa*; and *C. albicans* almost always indicate true infection, whereas CoNS, diphtheroids, and other typical skin microbiota should be questioned.
- More than one blood culture bottle growing the same organism usually indicates a significant isolate, whereas growth of an organism, especially one associated with skin microbiota, in a single bottle when multiple sets of blood cultures are obtained usually indicates that the isolate is a contaminant.
- Isolation of the same organism from the blood and from a normally sterile site in the same patient usually indicates that the organism isolated from the blood is a pathogen.

Rapid identification of microorganisms growing in blood cultures

Automated continuous-monitoring blood culture systems have taken the labor out of examining blood culture bottles for the presence of microbial growth, but these systems can determine only that something is growing in the bottle. The microbiologist must remove a flagged bottle from the instrument and process the fluid to determine whether a viable microorganism is present and identify it. A small amount of fluid is removed from the bottle and used to make a smear to be Gram stained and plated onto appropriate media, depending on microscopic morphology of the organisms observed on the Gram-stained smear. All initial procedures from the blood culture bottle should be performed in a biological safety cabinet using standard safety precautions.

An anaerobic blood agar plate should be subcultured from every positive bottle, aerobic or anaerobic, because anaerobes sometimes grow from aerobic bottles, and vice versa. The Gram-stained smear can be examined quickly, and the health care provider should be notified immediately of the positive blood culture result along with the morphology of the organism seen (e.g., gram-positive cocci, gram-negative rods, yeast). Definitive identification and susceptibility results are typically not available until isolated colonies grow on the subcultured plates, which usually takes 24 to 48 hours. During this time, the patient is given empiric antimicrobial therapy that may or may not be optimally effective for the isolate. The sooner the patient is treated with an effective antimicrobial

Fig. 36.2 Peptide nucleic acid (PNA) fluorescent in situ hybridization. Based on initial Gram stain of the positive blood culture, this method can identify commonly isolated organisms within 90 minutes. This example shows the differentiation of *Staphylococcus aureus* and coagulase-negative staphylococci (CoNS). *rRNA*, Ribosomal ribonucleic acid.

agent, the more favorable the outcome. To decrease the time it takes to identify a microorganism growing in a blood culture, several rapid methods are available.

Conventional rapid diagnostic tests

Biochemical and enzymatic tests and stains that can be performed directly from blood culture bottles include direct tube coagulase (to differentiate suspected *S. aureus* from CoNS), thermonuclease (a heat-stable DNase produced by *S. aureus*), oxidase, bile solubility and Quellung capsule stain (for suspected *S. pneumoniae*), and modified Kinyoun stain (AFB/*Nocardia*). These are presumptive, not definitive tests but can provide the health care provider with preliminary information. With the development of rapid and accurate molecular identification directly from blood bottles, these tests are rarely performed currently.

Fluorescence in situ hybridization

Fluorescence in situ hybridization targets ribosomal ribonucleic acid (rRNA) in an organism by using an oligonucleotide or peptide nucleic acid (PNA) probe with a fluorescent label. Although this is a molecular method, there is no amplification of nucleic acid involved. The procedure takes 1.5 to 3 hours to perform; the sensitivity of species-specific probes in one study was reported to be 97%, with 95% specificity. Different probes are available that target common organisms isolated from blood cultures, such as *S. aureus*, *Enterococcus* spp., and *Candida* spp. (Fig. 36.2).

Nucleic acid amplification methods

Several nucleic acid amplification tests (NAATs), using PCR to directly identify microorganisms growing in a blood culture, have been approved by the U.S. Food and Drug Administration (FDA) and are available. The Verigene system (Nanosphere, Northbrook, IL) amplifies nucleic acid targets that are then detected by hybridization of oligonucleotides bound to nanosphere particles with a silver staining process (Fig. 36.3). The FilmArray system (BioFire Diagnostics, Salt Lake City, UT) involves an initial nucleic acid extraction and purification followed by PCR amplification in a two-step process. The Verigene, FilmArray, and ePlex (GenMark Diagnostics, Carlsbad, CA) systems are multiplex assays that can identify a group of gram-positive and gram-negative organisms and yeasts, as well as several resistance genes, within 1.5 to a few hours. The GeneXpert system (Cepheid,

Fig. 36.3 Verigene test cartridge (Nanosphere, Northbrook, IL). Nucleic acid amplification testing can identify commonly isolated organisms and some species with resistance genes within 2 to 4 hours. Isolate from the blood culture bottle is inoculated into wells.

Sunnyvale, CA) also offers assays that detect resistance genes and is evaluating a molecular assay (XPert MTB/RIF) to detect *M. tuberculosis* directly from blood. Clinical trials have shown greater than 95% concordance for identification and drug resistance compared with conventional culture methods, resulting in a great reduction in time to reporting and appropriate treatment, costs, and hospital stays for patients. A disadvantage is that these methods do not perform well in the case of polymicrobial infections, and there is some ambiguity in the identification of certain groups of organisms. Therefore it is important to note that these methods do not replace conventional blood cultures but are used in conjunction with them.

Matrix-assisted laser desorption/ionization–time-of-flight mass spectrometry

Matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry identifies a wide variety of organisms, including fungi, fastidious bacteria, and anaerobes, in a matter of minutes, and it is routinely used in many modern microbiology laboratories. The Vitek MS (bioMérieux, Inc.) and the Microflex (Bruker, Billerica, MA) are instruments that use this technology (Fig. 36.4). The organisms must first be subcultured from the blood and isolated in pure culture. The FDA has not approved direct detection from blood, and there is currently no ability to determine antimicrobial susceptibility by using this method.

Biomarkers

Sepsis is the most common cause of admissions and death in intensive care units, and the rates are increasing. Sepsis is difficult to diagnose using clinical signs and symptoms. Some of the classic indicators of sepsis (i.e., elevated WBC count, fever, elevated CRP level, and hypotension) can be absent during sepsis. In addition, these indicators can occur in other systemic inflammatory conditions, including trauma and surgery, as well as from a response to various drugs and blood product transfusions. Although blood cultures are considered the gold standard, they are positive in only about one third of sepsis cases and generally require 3 to 5 days for a positive result to be obtained. Rapid accurate diagnosis of sepsis is

Fig. 36.4 Microflex matrix-assisted laser desorption/ionization–time-of-flight instrument (Bruker, Billerica, MA). This is a 48- to 96-organism per test plate that can identify isolates within 15 to 20 minutes. The organisms must first be grown in pure culture.

BOX 36.2 Biomarkers for sepsis

Some of the more commonly used diagnostic and/or prognostic biomarkers for sepsis are as follows:

- (1-3)- β -D-Glucan^a
- Lactate
- Procalcitonin
- C-reactive protein
- D-dimer
- Endocan
- Inducible protein 10
- Group IV phospholipase A2 type II
- Neutrophil gelatinase-associated lipocalin
- Lipopolysaccharide-binding protein
- Macrophage migration inhibitory factor
- Mature adrenomedullin
- Mer receptor
- Midregional proadrenomedullin
- Natriuretic peptides
- Copeptin
- Thrombopoietin
- Soluble triggering receptor expressed on myeloid cells 1
- Soluble urokinase-type plasminogen activator

^aMarker for invasive fungal infection.

critical for appropriate lifesaving treatment, and it is important to rule out sepsis to prevent unnecessary treatments. For these reasons, scientists have been looking for biomarkers to aid in the diagnosis. A biomarker is defined as an objectively measured characteristic that indicates a normal biological or pathogenic process, or pharmacologic response to therapy.

Over 175 different biomarkers for sepsis, with diagnostic and/or prognostic value, have been reported in the literature (Box 36.2). The goal of such a marker is to distinguish between sepsis and any other SIRS. Procalcitonin, a peptide released in response to proinflammatory stimuli, is regarded

as a potential biomarker for sepsis. In a large meta-analysis, it had a reported sensitivity of 77%. If the test were used alone to diagnose sepsis, 23% of the patients with a sepsis would have a negative result and would not receive antimicrobial therapy. The reported specificity was 79%; that is, 21% of the patients without sepsis would test positive and would undergo unnecessary treatment. It is clearly not an ideal test in several clinical situations, and many health care providers are reluctant to make treatment decisions based solely on procalcitonin test results.

Because individual biomarkers seem to have poor predictive ability in diagnosing sepsis, scientists and health care providers have turned to combinations of biomarkers. For example, serum lactate (lactic acid) has been found to be helpful in indicating severe sepsis, particularly when used with CRP or procalcitonin levels. Other studies have reported on numerous combinations with as many as six different biomarkers. The combination assays had a better predictive value than any one biomarker. Currently, health care providers use clinical signs and symptoms along with the results of a select number of biomarkers to guide therapy. Research is still needed to determine which markers and which combinations provide the best diagnostic value.

Treatment

Sepsis being such a complex disorder, it is expected that many therapeutic options are needed to alleviate this devastating clinical event. Several treatment modalities have been tried, but some are not always successful.

Antimicrobial therapy

Antimicrobial agents remain the mainstay of treatment of bacteremia. Because of the potentially devastating consequences of untreated bacteremia, therapy is frequently instituted empirically on the basis of clinical signs and symptoms before bacteremia has been confirmed by a positive blood culture or before the causative agent has been definitively identified. The choice of initial therapy is based on the likely identity of the infecting microorganism (according to the patient's clinical syndrome), presence of comorbid conditions that might affect the risk of infection with particular bacterial species (e.g., cancer), patient's immune status, recent environmental exposures (e.g., hospitalization that might have resulted in colonization by resistant organisms), and prior antimicrobial therapy, which might have selected for resistant pathogens. Broad-spectrum antimicrobial agents are frequently used for initial empiric therapy, and a combination of agents may be used to ensure coverage of several possible pathogens.

After identification of organisms cultured from blood and determination of antimicrobial susceptibility, initial therapy may be more narrowly targeted, thus allowing use of the most effective agent against the responsible pathogen while minimizing the potential for adverse reactions and emergence of antimicrobial resistance. For bacteremia caused by some pathogens (e.g., *E. faecium*, *P. aeruginosa*), a cell wall-active agent, such as a β -lactam, is combined with an aminoglycoside, resulting in a synergistic antimicrobial effect and improved clinical outcome. Along with antimicrobial therapy, adjunctive measures, such as drainage of infected

fluid and removal of an infected intravascular catheter, may be essential to achieving cure of the infection. Treatment of comorbid conditions, such as diabetes, is helpful in gaining control of infection. Finally, measures aimed at restoring immunocompetence—such as administration of cytokines that increase the number of circulating neutrophils in patients who are immunosuppressed because of cancer chemotherapy—are critical in complementing antimicrobial therapy.

Antisepsis therapy

Because of the high mortality of septic shock, whether or not accompanied by bacteremia, a number of therapies aimed at blocking the cascade of events that result in sepsis, shock, and death have been studied and evaluated. These therapies described here are invariably used in combination with antimicrobial agents. Unfortunately, even with treatment, 30% to 50% of patients with sepsis die, usually because of underlying illnesses in addition to their sepsis.

Physiologic support

Resuscitation with IV fluids to maintain tissue perfusion is a fundamental method for management of the patient with sepsis. In patients with septic shock who do not respond to fluid support, pressor agents may be used to ensure an adequate blood pressure. Along with fluids, respiratory therapy with oxygen is used to support patients with sepsis.

Anticoagulation agents

Because the consequences of bacteremia and sepsis may include activation of the coagulation cascade with resultant DIC and decreased tissue perfusion, the use of anticoagulants has been studied for the treatment of sepsis. One agent, drotrecogin alfa, also known as *activated protein C*, has been shown in clinical trials to decrease mortality in patients with septic shock. Drotrecogin alfa inhibits factors Va and VIIIa of the coagulation cascade, thereby inhibiting coagulation. Drotrecogin alfa may also decrease chemotaxis of WBCs by interfering with the interaction between the leukocytes and endothelium of blood vessels. Because of the potential bleeding complications, this therapy is restricted to use in patients who are at the highest risk of death. It is not effective for less severely ill patients. Other anticoagulant therapies, such as antithrombin III therapy, have not been effective in the treatment of sepsis.

Glucocorticoids

Because of their potent anti-inflammatory action, glucocorticoids have long been of interest in the treatment of sepsis. Although early studies of high-dose glucocorticoids showed benefit in septic patients, a randomized controlled trial in the late 1980s showed no advantages to the use of glucocorticoids over placebo in severely ill patients with sepsis, and their use was abandoned. More recently however, the use of glucocorticoids has made a cautious comeback based on controlled trials of low doses of these agents to treat adrenal insufficiency associated with sepsis rather than to block inflammation.

Case check 36.4

The bacterium isolated from the patient in the Case in Point was a CoNS. Initially, the patient was given broad-spectrum antimicrobial agents, based on the initial report of gram-positive cocci in clusters seen on Gram-stained smear. However, once the organism was identified and susceptibility testing performed, treatment was changed to more appropriate antimicrobials to minimize the potential for adverse side effects or emergence of resistance.

Anticytokine therapies

A large number of investigational agents aimed at blocking the action of tumor necrosis factor and other cytokine mediators of sepsis have been studied in the treatment of sepsis. Despite an apparently sound theoretic rationale and promising results in animal models, these therapies have not proven effective in clinical trials.

Prevention

Prevention of community-acquired bacteremia has been aided by immunizations. Pneumococcal and Hib vaccination have been effective in preventing invasive infections caused by *S. pneumoniae* and *H. influenzae*, respectively, and vaccination for viral pathogens (e.g., influenza virus, varicella virus) has helped lower the incidence of invasive secondary infections caused by bacterial pathogens, such as *S. aureus* and *S. pyogenes*. In the hospital setting, prevention of healthcare-associated bacteremia revolves around minimizing iatrogenic infections from indwelling intravascular catheters and other invasive devices by following recommended infection control practices. The use of antimicrobial-coated central venous catheters has been shown to decrease rates of CRBSIs. Some hospitals currently screen and treat patients colonized by some organisms, such as MRSA, VRE, and resistant gram-negative rods, before surgery to lessen the risk of these patients developing bacteremia after surgery.

POINTS TO REMEMBER

- Patients who are immunocompromised are at greatest risk for bacteremia and the systemic complications that may follow.
- Most bacteremia cases in the United States are caused by gram-positive organisms, although gram-negative organisms are increasing and represent a large proportion of cases.
- Fungal agents are significant causes of bloodstream infections (fungemia).
- Time of collection, frequency of obtaining, and volume of blood for culture are critical components for optimal recovery of microorganisms.
- Instrumentation for laboratory diagnosis of bacteremia continues to become more rapid and sensitive for the detection of organisms present in blood cultures.
- Rapid diagnostic tests for the identification of organisms in blood are widely available.
- A combination of biomarker test results along with clinical signs and symptoms might provide a rapid and accurate diagnosis of sepsis.
- Antimicrobial agents remain the mainstay of treatment of bacteremia.

LEARNING ASSESSMENT QUESTIONS

1. Which form of bacteremia is demonstrated in the Case in Point?
2. What condition has placed the patient at an increased risk for bacteremia?
3. Which other risk factors favor bacteremic episodes in certain patient populations?
4. What are the most common sources of bacteremia?
5. Which bacterial organisms in pneumonias produce concurrent bacteremia?
6. What are the major consequences of bacteremia?
7. What are treatment methods for bacteremia?
8. Who is at risk for polymicrobial bacteremia?
9. Why is it important to keep the ratio of blood to culture medium to 1:10?
10. How many sets of blood cultures should be collected, and how often should they be collected for maximum recovery of infecting agents?

Pyelonephritis

Pyuria

Ureteritis

Urethritis

Urinary tract infection (UTI)

Case in point

A 26-year-old female patient presented to the urgent health clinic with complaints of urinary frequency, dysuria, hematuria, and severe lower back pain. She was febrile and slightly tachycardiac but otherwise unremarkable. She had previous urinary tract infections (UTIs) 3 and 7 months before the current presentation, which were treated initially with ampicillin but went unresolved until a combination of nitrofurantoin and doxycycline were used. Given her past medical history, complaints of back pain, and clinical findings, she was sent to the local hospital for further observation. While at the hospital, she became delirious, and her blood pressure decreased. A sepsis and urine workup was initiated. A complete blood count showed elevated white blood cells, and a urine dipstick was positive for blood and a pH of 6.5. A microscopic analysis revealed bacteria without casts. Bacterial culture was performed by plating the urine to sheep blood and MacConkey agar plates. Growth of 100,000 colony-forming units (CFU) per mL was observed on sheep blood agar only. Gram-stained smear of the colonies revealed gram-positive cocci in clusters. The final identification

OBJECTIVES

After reading and studying this chapter, you should be able to:

- Discuss various infections that occur in the urinary system.
- Associate the clinical signs, symptoms, and parameters with each of the disease manifestations.
- Identify the epidemiology and risk factors associated with the development of a urinary tract infection (UTI).
- Identify the organisms associated with UTIs.

was *Staphylococcus aureus*, and blood cultures were flagged as positive the same day with the same organism.

Issues to consider

After reading the patient's case history, consider:

- The difference between a single-episode UTI and recurrent UTIs
- Different ways patients present with a UTI
- The value of urinalysis in diagnosing UTI
- The value of obtaining a blood culture in suspected pyelonephritis cases
- The common causative agents of UTIs

Introduction

Urinary tract infections (UTIs) are among the most common bacterial infections affecting humans, accounting for up to 7 million episodes of **cystitis** and 250,000 episodes of **pyelonephritis** infections in the United States annually. Accurately assessing the incidence of UTIs is difficult because they are generally not reportable diseases. Diagnosis depends on patient signs and symptoms as well as urinalysis and urine culture results. The most common presentation is presence of blood in the urine (**hematuria**), pain during urination (**dysuria**), and increased urinary frequency. In the outpatient setting, however, diagnosis is usually made without the latter. UTIs occur more frequently in women than in men, with up to 50% of all women experiencing a UTI during their lifetime. Those at risk for UTI include older adults, pregnant women, patients who have had renal transplantation, patients with spinal cord injuries, patients with bladder catheters, and patients with genitourinary (GU) tract abnormalities.

There are two clinical schemas for classifying UTIs: (1) single versus recurrent episode and (2) complicated versus uncomplicated episode. A single-episode UTI occurs once and does not recur. Patients with chronic or recurrent UTIs have repeated episodes of urinary infections caused by bacteria (**bacteriuria**), with or without clinical manifestations. These episodes are arbitrarily divided into relapse and reinfection. The former involves the same organism and implies a focus of infection in the renal or prostatic parenchyma; the latter implies a different organism and is usually limited to the bladder. In the clinical history of a patient, a general rule is that prior UTIs within 6 months or less from the current episode are highly likely to involve the same organism. This correlation is helpful in deciding empiric treatment and possibly determining if the source of the infection occurs from bacteria being introduced into the system via a urethral or a GU abnormality or if the infectious agent is present elsewhere in the body and is being "seeded" into the urinary tract.

Case check 37.1

A single-episode UTI occurs once, with no repeated episodes. These cases are usually not associated with GU abnormalities. Recurrent UTIs occur as repeated episodes of bacteriuria, with or without clinical manifestations. They can occur as relapse when the same infectious agent is identified or as reinfection with different organisms.

Uncomplicated UTIs occur primarily in sexually active young women and adults with normal GU tracts and no prior instrumentation; these infections are usually caused by antimicrobial-susceptible bacteria. Complicated UTIs occur in individuals who have one or more structural or functional GU abnormalities or have indwelling catheters and whose conditions cannot be controlled with therapy.

Bacteriuria, which can be symptomatic or asymptomatic, is the presence of bacteria in urine. Asymptomatic bacteriuria (ASB) is the presence of bacteria in urine in significant quantities, but without GU signs or symptoms of infection. ASB requires treatment only in some populations, such as pregnant women and patients about to undergo instrumentation of the GU tract. Disease occurs when the multiplication of organisms in the urinary tract interferes with the normal function of the involved organ. It is important to remember that infection is defined by clinical parameters and urinalysis, not solely by quantitation or identification of microbes. In fact, as more organisms are discovered, there may be several fastidious or unculturable microbes that cause ASB and UTIs.

Anatomic considerations

The urinary system includes the kidneys, where urine is formed as a plasma filtrate; the ureters, which drain urine to the bladder; the bladder; and the urethra, which excretes urine from the bladder (Fig. 37.1). In addition, the prostate gland in males is considered part of the urinary tract. The only other significant difference between the male and female urinary tract is the length of the urethra—about 4 cm in women and 20 cm in men. Because most UTIs result from microorganisms ascending the urethra, women are at greater risk for UTIs than men. Except for the urethral mucosa and the renal medulla, which appear to be relatively more susceptible to infection, the normal urinary tract is resistant to colonization and subsequent infection by bacteria. The urinary tract efficiently and rapidly eliminates virulent and avirulent microorganisms. The urinary tract is normally regarded as a sterile site; however, the urethra can be transiently colonized by microorganisms.

Fig. 37.1 Anatomy of the urinary tract, with corresponding terms and diseases. L-UTI, Lower urinary tract infection; U-UTI, upper urinary tract infection.

Although urine is frequently considered a good medium for bacterial growth, the extremely high urine osmolarity and low pH inhibit the growth of many uropathogens and almost all normal urethral microbiota. In addition, very dilute urine fails to support the growth of most bacterial species. Urine from men is more inhibitory than urine from women because of the bactericidal effect of prostatic fluids in the urine of men as well as the difference in pH and osmolarity, leading to another reason that women have a higher incidence of UTIs.

Factors such as high ammonia concentration, hyperosmolarity, lowered pH, and sluggish blood flow in the renal medulla can contribute to reduced leukocyte chemotaxis and bactericidal activity of WBCs, resulting in lowered resistance to infection. Urine has also been shown to inhibit the migrating, adhering, activation, and killing functions of polymorphonuclear cells. However, the presence of acid-labile mucopolysaccharides that inhibit bacterial adherence along with the flushing action of the bladder provide additional defensive mechanisms along the lower urinary tract

that overcome these immunosuppressive effects. In certain cases, such as postsurgical improper draining of a catheter, anatomic abnormalities, or calculi formation (kidney stones), urinary retention may be a significant contributing factor to UTI development. Table 37.1 lists the comparative physiologic parameters of urine for healthy individuals and those with cystitis and pyelonephritis.

In most cases, the pathogenesis and course of UTIs are determined by the anatomy of the organs involved. UTIs can be distinguished by location into upper and lower UTIs. Upper UTIs (U-UTIs) involve the renal parenchyma (**pyelonephritis**) or the ureters (**ureteritis**). Lower UTIs (L-UTIs) involve the bladder (**cystitis**), the urethra (**urethritis**), and in males, the prostate (**prostatitis**). Urethritis and cystitis are the most common types of UTIs. The heterogeneity of disease presentation, management, and prognosis is reflected in the terminology of UTIs. Box 37.1 lists terms and definitions frequently used in connection with UTIs. Each has specific criteria and must be used appropriately.

Table 37.1 Comparative parameters for urine in control individuals and patients with urinary tract infections

Parameter	Ranges		
	Reference value	Abnormal	
		Cystitis	Pyelonephritis
Urine dipstick			
Specific gravity	1.001–1.035		
pH range	4.7–8.0 (6.0 average)		
Protein	Negative to trace		Increased
WBC esterase	Negative	Positive	Positive
Nitrite	Negative	Positive	Positive

BOX 37.1 Terms and abbreviations commonly used for urinary tract conditions

Acute urethral syndrome. Also known as *abacterial cystitis*, includes urinary frequency, dysuria, and pyuria. It is sometimes defined as the presence of more than 8 leukocytes/ μ L in uncentrifuged urine or approximately 2 to 5 leukocytes per high-power field present in centrifuged urine sediment accompanied by urine cultures negative for bacteria.

Bacteriuria. The presence of detectable bacteria in the urine. Patients may be symptomatic or asymptomatic (e.g., geriatric or pregnant patients).

Cervicitis. Inflammation of the cervix; it may present as acute or chronic. Causative agents include sexually transmitted organisms, such as *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Symptoms include dysuria, urinary urgency, vaginal discharge, and low back pain.

Cystitis. Inflammation of the bladder, presenting as dysuria and urinary frequency and urgency. It is often caused by gram-negative bacilli, such as *Escherichia coli*, *Proteus* spp., and *Klebsiella* spp. It occurs more frequently in women than in men. It can also be caused by medication and certain viruses, such as the adenovirus.

Dysuria. Pain during urination. Often felt as a burning sensation, but may present differently for each person.

Hematuria. Presence of blood in the urine. This can be visible or may be only detected on urine dipstick or microscopic examination. More common in upper UTIs than in lower UTIs.

Lower urinary tract infection (L-UTI). A GU tract infection limited to the urethra (urethritis), bladder (cystitis), and in males, the prostate (prostatitis). These infections generally appear in adults with dysuria, increased urinary frequency and urgency, and occasionally suprapubic tenderness.

Prostatitis. A GU infection in males that involves the prostate; fever is often present.

Pyelonephritis. Infection in the kidney. This is often caused by infection in the lower tract ascending to the kidney. Symptoms include fever, chills, nausea, vomiting, lower back tenderness, and dysuria. It can be due to hematogenous spread by bacteremia.

Upper urinary tract infection (U-UTI). A GU tract infection limited to the renal parenchyma (pyelonephritis) or the ureters (ureteritis). It is often accompanied by L-UTI symptoms in addition to costovertebral flank pain or tenderness and fever. At times, L-UTI precedes the appearance of fever and U-UTI by 24 to 48 hours.

Urethritis. Inflammation of the urethra, presenting as dysuria and discharge. Causative agents include *N. gonorrhoeae* and *C. trachomatis*. Other causes include trauma, allergies, or chemical factors.

Urinary tract infection (UTI). A spectrum of diseases caused by microbial invasion of the GU tract that extends from the renal cortex of the kidney to the urethral meatus (see Fig. 37.1).

pregnancy as an adult. This necessitates extensive evaluation to identify underlying functional or anatomic abnormalities. During the neonatal period, about 1% of all infants have bacteria in their urine. The incidence is higher in boys, and bacteremia often is present. A meta-analysis from children across Europe showed that during childhood, especially in the first 12 months of life, a 5% rate of UTIs occurs. The rate of UTIs in neonates 2 weeks of age and younger is higher if in the intensive care unit (ICU) and can correlate with the presence of otherwise unexplained jaundice and sepsis. In addition, autopsies have shown a predominance of infection in infant boys with pyelonephritis.

Strong evidence exists indicating that circumcision may confer a protective effect against UTIs in male infants. Non-circumcised infants younger than 6 months of age were shown to have a 12-fold increased risk of UTI compared with circumcised cohorts. Among preschool-age children, girls develop UTIs more often compared with boys, and infection is frequently associated with severe congenital abnormalities. These infections often do not manifest any symptoms. It is believed that most of the renal damage caused by a UTI occurs in this age group. Among school-age girls, in whom UTIs go into long-term remission spontaneously or through antimicrobial therapy, many develop symptomatic infection after they engage in sexual activity, and these infections occur at a far higher rate than in the general population. Thus the presence of bacteria in urine in childhood defines a population at higher risk for the development of UTIs in adulthood.

Adults to 65 years of age

From adulthood to 65 years of age, the incidence of UTIs in men is extremely low. When infections do occur, they often are associated with anatomic abnormalities or prostatic disease and consequent instrumentation, such as catheterization. Among women in this age group, however, as many as 20% experience a UTI with associated symptoms. Women without catheters, and who are sexually active, tend to experience more UTIs than those practicing abstinence.

Geriatric population

The diagnosis and management of UTIs in the geriatric population can be challenging. Older adults frequently have an atypical clinical presentation, including delirium, fever, hypothermia, or failure to thrive. Geriatric patients also have more comorbidities (two or more unrelated diseases or coexisting medical problems) and an increased risk of drug interactions.

In patients older than 65 years of age, the incidence of UTIs increases dramatically for both sexes, but with a progressive decrease in the female-to-male ratio. The increased incidence of UTIs in men arises from obstructive uropathologic conditions caused by the prostate and from the loss of the bactericidal activity of prostatic secretions. In women, bladder prolapse contributes to the occurrence of infection, as does soiling of the perineum from fecal incontinence in women with dementia and estrogen deficits causing changes to the vaginal biota. In both men and women, neuromuscular disease, decreased relative mobility, and increased instrumentation and bladder catheterization are

Epidemiology and risk factors

Age

Children

UTI in children is associated with great morbidity and long-term medical problems, including impaired renal function, hypertension, end-stage renal disease, and complications of

contributing factors. UTI is a common cause of bacteremia in older adults.

The time course of UTIs is shown in Fig. 37.2. The epidemiology of UTIs is influenced by the pathophysiology of the infection and by other factors, such as the virulence of the infecting organisms and their inherent mechanisms of pathogenicity, the person's immune status, and other selective external pressures. Box 37.2 lists well-defined microbial virulence factors, and Table 37.2 presents nonspecific and GU-specific factors that affect host defense and the immune system's ability, humoral and cellular, to resist infection. The dynamic interaction that exists among these factors is continually changing.

The severity of infection cannot be defined by the type of invading organism or by colony counts alone; the complete clinical situation must be assessed. Predisposing factors that may affect a person's risk of developing a UTI include presence of an indwelling catheter, or intermittent catheterization; urinary tract instrumentation, manipulation, or structural abnormality; and underlying disorders or comorbidities, such as diabetes mellitus. Other underlying risk factors include sexual activity in younger women and incontinence in the geriatric age group. Nonspecific factors that can significantly enhance the risk for infection directly or indirectly, include smoking and the use of birth control pills, alcohol, or antimicrobial agents. Common urinary pathogens in older adult populations include *S. aureus*, enterococci, and *Proteus mirabilis*, particularly in patients with catheter-associated urinary tract infections (CAUTIs).

Fig. 37.2 Frequency of urinary tract infection over time. O-O, Males; X-X, females.

BOX 37.2 Microbial virulence factors

- Adherence (bacterial adhesions)
- Biofilms
- Capsular polysaccharides
- Hemolysins
- Lipopolysaccharides
- Mobility (flagella and chemotaxis responses)
- Toxin production

Case check 37.2

Patients can present with UTI differently based on age, location of infection, and underlying conditions or comorbidities. Children younger than 2 years may present with failure to thrive, vomiting, and lethargy. Children older than 2 years may complain of dysuria and abdominal pain. Adults may complain of dysuria, urgency, frequency, and suprapubic pain. They might have fever, nausea and vomiting, flank pain, and pyelonephritis. Older patients can have delirium, weakness, and failure to thrive; transplant patients may have pain at the graft sites as well as changes in mentation.

Institutionalized care

Hospitalized patients and those residing in long-term care facilities develop UTIs more often compared with outpatients. The generally ill condition of patients in health care institutions, higher probability of urinary tract instrumentation, and higher incidence of GU tract anatomic or functional abnormalities are major contributors to this difference.

ASB is a common and usually benign condition in this population. Neurogenic bladder and incontinence increase the frequency of ASB. It can be difficult to distinguish ASB from a symptomatic infection. In one study of nursing home patients with fever, a UTI was the cause in only 10%. However, most patients had a positive urine culture result because of the underlying ASB. A serious cause of fever, such as pneumonia, bacteremia, or abdominal infection, can be missed if the clinical assessment stops with a urinalysis and a positive urine culture.

Table 37.2 Host defenses and external selective pressures influencing the outcome of interactions between bacteria and the urinary tract

Parameter	Nonspecific	Genitourinary specific
Host defense	- Intact skin - White blood cell function (e.g., phagocytosis) - Age - Neoplasia - Immune competence - Hormonal changes - Pregnancy - Malnutrition - Malaria, diabetes - Psychological state - Immunodeficiency syndrome	- Diabetes mellitus - Pregnancy - Sickle cell anemia (black women) - Neuromuscular diseases - Structural abnormality - Gout (?) - Hypertension (?) - Potassium deficiency (?) - Urine pH - Urine flow amount - Urinary tract mucosa
Selective pressures	- Birth control pills - Smoking - Alcoholism - Anesthesia - Drug addiction - Immunosuppressive drugs - Irradiation, therapeutic - Antimicrobial therapy	- Sexual activity - Incontinence - Bladder catheterization, indwelling or intermittent - Instrumentation - Urinary stones - Urine retention

Pregnancy

Pregnant women are at higher risk for UTI for several reasons. Hormonal changes lead to changes in the ureter and urethra, making them more susceptible to bacterial adherence and infection. In addition, the enlarging uterus can put pressure on the bladder and impair urinary flow, leading to cystitis or pyelonephritis. ASB also may occur, but in pregnant women this should be treated because infection can lead to premature labor as well as infectious complications in the fetus or the newborn. Susceptibility testing is particularly important in this patient population because not all antimicrobials can be given to pregnant women. This is particularly true of drugs such as quinolones, which are a standard treatment for UTIs in the general population. Pregnant women should be screened closely for signs of a UTI and, at the third trimester, be screened again for organisms that can cause UTIs and be transmitted during vaginal delivery of her child. Early identification and treatment of UTI in pregnant women has decreased the incidence of preterm birth and low-birth-weight neonates.

Renal transplantation

For decades, the number of kidney transplantations in the United States has continued to increase, with nearly 25,000 transplants occurring in 2021. Although kidney transplantation can be lifesaving and improve quality of life, significant complications can occur, including infection of the urinary tract. UTI is the most common infection in kidney transplant recipients, occurring in up to 86% of recipients. Several factors contribute to this increased risk of UTI, including significant immunosuppression; foreign bodies, such as stents and urinary catheters; stricture; obstruction; scarring or other abnormalities of the ureter and urethra; graft trauma; and diabetes mellitus. In fact, having a ureteral stent can increase the risk of UTI by 1.5-fold in this population. In addition, because these patients are receiving trimethoprim-sulfamethoxazole prophylaxis for *Pneumocystis* pneumonia as well as for UTIs, they can develop infection with organisms resistant to this antimicrobial.

UTIs in kidney transplant recipients most often present as cystitis; however, almost 25% of cases may present as pyelonephritis and can lead to allograft injury. In addition, UTIs may be responsible for more than 50% of bacteremias in this population. These patients might have atypical presentations, lower colony counts, and variable pyuria. *Escherichia coli* and other gram-negative bacilli account for up to 90% of the pathogens in culture positive UTIs in kidney transplant recipients. However, some transplantation centers are now reporting a rise in enterococcal UTIs, particularly in the first month after transplantation.

Bladder catheterization

UTIs are the most common healthcare-associated infections, accounting for approximately one third of these infections. Up to 95% are related to bladder catheterization and/or manipulation. In a catheterized patient, the risk of acquiring a UTI depends on the duration of catheterization, appropriate catheter care, and host susceptibility. Bacteriuria will inevitably occur, given enough time, because the mechanisms of

infection and colonization involve intraluminal and extraluminal migration of bacteria. The most common pathogens include enteric gram-negative bacteria (particularly *E. coli*), enterococci, yeasts, and staphylococci. Candiduria is a common finding in patients with long-term catheterization, and its clinical relevance is difficult to determine and controversial, particularly in asymptomatic patients.

Hospitals and long-term care facilities implement protocols to care for and monitor patients with catheters to ensure that UTIs are not associated with prolonged use of a bladder catheter. Infections associated with catheters (i.e., CAUTIs) are reportable to accreditation and government agencies. When facilities have a higher-than-normal CAUTI rate, this affects the overall “score of care” and the insurance reimbursement rates it receives for patient care. Certain professional organizations, such as the Infectious Diseases Society of America (IDSA), have published guidelines to reduce CAUTI occurrence and manage patients with CAUTIs and catheter-associated ASB infections.

Sexually transmitted infections

Although most sexually transmitted infections (STIs) involve the genital tract, the anatomic proximity to the vagina in females and the shared tract in males lends itself to UTIs caused by the same organisms implicated in an STI. Often, the symptoms of STIs and UTIs are shared, and the infected person may present with complaints of either a urinary tract or genital tract infection. Most organisms that cause STIs are fastidious; therefore routine urine culture methods may not recover these organisms. In a study of female patients presenting to an urban emergency department, STI-associated organisms were found in 17% of urine cultures collected by catheterization; of these, they had colony counts that would exclude reporting them based on widely shared microbiology laboratory guidelines. Some organisms, such as *Mycobacterium*, *Chlamydia*, and *Ureaplasma* species, can cause UTIs secondary to STIs but cannot be cultured or would be difficult to grow, making sensitivity of detection on urine cultures extremely poor. A UTI secondary to an STI should be considered if the patient is sexually active, has multiple partners, has a past medical history of STIs with unresolved clinical symptoms after empiric therapy, and has negative urine cultures.

Clinical signs and symptoms

UTIs in children younger than 2 years of age usually manifest with nonspecific symptoms, such as failure to thrive, vomiting, lethargy, and fever. Children older than 2 years of age are more likely to complain of more localized symptoms, such as dysuria, frequency, and abdominal pain.

Adults with uncomplicated lower UTIs limited to the urethra or bladder present primarily with dysuria, often in combination with frequency, urgency, suprapubic pain, and hematuria. Each episode of uncomplicated UTI in women is usually associated with 1 week of symptoms. An acute, complicated UTI presents with the same symptoms seen in uncomplicated UTIs with the exception of lower back and/or flank pain associated with pyelonephritis may be reported. Patients with U-UTIs, such as pyelonephritis, may also present with nausea, vomiting, fever, chills, night sweats, and

costovertebral angle tenderness. These symptoms may occur in the presence or absence of symptoms of cystitis. Dysuria and frequency may precede the onset of upper urinary tract and systemic symptoms by 1 or 2 days.

Bacteremia, when present, may help confirm a diagnosis of pyelonephritis. However, presenting symptoms of UTI can differ widely. Cases of pyelonephritis may be asymptomatic, manifest symptoms such as those of lower UTIs, or present as life-threatening sepsis. Most older adult patients have atypical presentations, such as delirium, failure to thrive, and/or weakness. Transplant recipients also may present atypically and might have pain at the allograft site.

Although dysuria is the most common reason for obtaining a urine specimen for culture, this clinical presentation is neither sensitive nor specific. Dysuria may be present in infections with herpes simplex virus, BK virus in kidney transplant patients, adenovirus, cytomegalovirus, *Ureaplasma*

urealyticum, *Chlamydia trachomatis*, or *Neisseria gonorrhoeae*. These agents are not detected by routine bacteriologic urine culture. Many noninfectious conditions, including urethral inflammation from physical or chemical agents or because of trauma, may have similar symptoms. Flank pain and fever without lower urinary tract symptoms, and bacteremia without urinary tract symptoms can be seen in patients with indwelling urinary catheters. Fig. 37.3 depicts an evaluation scheme for women with acute dysuria.

Causes of urinary tract infections

Pathogenesis

Bacteria can gain access to the urinary tract by the ascending route or the hematogenous (or descending) route. Women

Fig. 37.3 Evaluation of women with acute dysuria. KOH, Potassium hydroxide.

usually acquire UTIs via the ascending route. Because of a shorter ureter in women, bacteria are easily introduced into the bladder through sexual intercourse or proximity of the urethral opening to the anus. Once established in the bladder, bacteria ascend the ureters, probably aided in many cases by the inflammation of the GU tract musculature. Some of the most common etiologic agents in UTIs also are motile because of flagella, which is theorized to aid in movement upward into the urinary tract.

U-UTIs caused by many species of gram-positive bacteria, mycobacteria, and fungi occur via hematogenous spread. Isolation of these organisms should alert a health care provider to consider sepsis and determine the primary source of the infection, as the UTI is a secondary manifestation (refer to the Case in Point). Gram-negative infections via the hematogenous route are more difficult to assess. Of these possible routes of infection, the ascending route is of paramount importance and most often associated with gram-negative bacteria. The hematogenous route is a less frequent but significant pathway with long-reaching implications including bacteremia and heart valve infections.

Causative agents

The normal bacterial biota of the skin, which includes the area surrounding the urethra, consists mostly of *Staphylococcus epidermidis*. Table 37.3 presents the organisms that do not grow well in urine and are not common causes of UTIs, arranged in descending order by age or patient status. Those listed first are found most commonly, and those at the end are less frequently isolated. Box 37.3 lists the more readily recognized agents of UTIs and emerging uropathogens that must be

recognized given the dynamics of urinary tract pathogens, population at risk, and selected pressures, as noted earlier. These organisms present unique challenges to clinical microbiologists.

Gram-negative bacilli

Of the Enterobacterales, antimicrobial-susceptible strains of *E. coli* that exist in the patient's fecal biota cause the majority of uncomplicated UTIs. As antimicrobial-resistant members of the Enterobacterales become more common, UTIs with multidrug-resistant bacteria are also increasing. Hospitalization and catheterization duration increases the risk of developing an infection with other organisms, such as *Pseudomonas aeruginosa*, *Acinetobacter* spp., *Proteus* spp., *Klebsiella oxytoca*, and *Enterobacter* spp. Infections can be polymicrobial, especially in complicated UTIs, and can yield urine cultures that are positive for multidrug-resistant organisms. Though not as common, group B *Streptococcus* (GBS) in pregnancy can pose a problem. Vaginal colonization of GBS is associated with neonatal sepsis with meningitis, preterm rupture of membranes, and early labor. Screening for GBS is part of routine prenatal health care.

Gram-positive cocci

Among the gram-positive cocci, *Enterococcus faecalis*, *Enterococcus faecium*, and *Staphylococcus saprophyticus* are the most commonly encountered causative agents. Enterococcal UTIs occur primarily in older men, particularly in association with urinary tract manipulation or instrumentation or prostatic hypertrophy. *S. saprophyticus* is found predominantly in

Table 37.3 Microbiota of normal voided urine^a defined by patient's age and status

Patient age, status	Usual biota
Neonate	Sterile
1–3 days of age	Staphylococci Enterococci Diphtheroids <i>Mycobacterium smegmatis</i>
Prepubertal	Micrococci Streptococci (α-hemolytic and nonhemolytic) Coliforms Diphtheroids
Adult	<i>Lactobacillus acidophilus</i> <i>Staphylococcus epidermidis</i> Streptococci (α-hemolytic and nonhemolytic) <i>Escherichia coli</i> Diphtheroids Yeasts Anaerobic streptococci <i>Listeria</i> spp.
Pregnancy	<i>Lactobacillus acidophilus</i> <i>S. epidermidis</i> Yeasts
Postmenopausal	Resembles prepubertal biota

^aUsually sterile or fewer than 1000 colonies/mL.

BOX 37.3 Recognized microbial agents of urinary tract infections

Common agents

Enterobacterales (especially *Escherichia coli*)
Enterococci (including vancomycin-resistant enterococci)
Streptococcus agalactiae (group B *Streptococcus*)
Pseudomonas spp.
Staphylococcus aureus
Staphylococcus saprophyticus
Candida spp.

Less common agents

Gardnerella vaginalis
Ureaplasma urealyticum
Mycoplasma hominis
Mobiluncus spp.
Leptospira spp.
Mycobacterium spp.
Chlamydia trachomatis (in males)

Agents often associated with multisystem diseases

Salmonella (with gastroenteritis)
Schistosoma haematobium
Cryptococcus neoformans
Trichosporon beigeli
Trichomonas vaginalis
Aspergillus spp.
Penicillium spp.
Adenovirus
Herpes simplex virus

Table 37.4 Urinary tract infections caused by coagulase-negative staphylococci

Characteristics of infections	Organism	
	<i>S. epidermidis</i>	<i>S. saprophyticus</i>
Sex of affected patient	Men and women equally	Women 95%, 16–35 years of age
Population at risk	Hospitalized patients with urinary tract complications	Healthy outpatients
Incidence	Common—20% or more of all UTIs for hospitalized patients >50 years of age	Uncommon—3.5% or fewer of all UTIs in hospitalized patients
Presentation	90% asymptomatic	90% symptomatic; indistinguishable from <i>Escherichia coli</i> UTIs
Therapy	Often resistant to multiple drugs	Responds readily to traditional urinary tract antimicrobials except nalidixic acid
Outcome	Bacteriuria often persists after therapy	Relapse rare; occasional reinfection

UTI, Urinary tract infection.

symptomatic sexually active women younger than 40 years of age. *S. epidermidis* is found in hospitalized patients older than 50 years of age. These individuals usually have had recent urinary tract surgery, indwelling urinary catheters, or chronic urinary tract disease. *S. epidermidis* is associated with UTIs in only about 20% of cases, and it is debatable if it is truly the causative agent. Table 37.4 highlights important clinical features of *S. epidermidis* versus *S. saprophyticus* presentation and demographics in UTIs.

S. aureus is also an important uropathogen. This bacterium is usually directly correlated with seeding from another system, such as blood (hematogenous route), and warrants additional investigation such as blood cultures and imaging studies to locate the primary source of infection. Because methicillin-resistant *S. aureus* is common, the relevance of isolation in urine cultures is acutely important in management of patient treatment and care.

Gram-positive bacilli

In rare cases, *Listeria monocytogenes* can be isolated from the urine of infants who acquired a perinatal infection with this organism and in 1% of patients with a systemic infection or renal transplant. *L. monocytogenes*, diphtheroids, and mycobacteria cause diseases predominantly in selected patient populations and often in association with a bacteremia. If any of these organisms are recovered from urine, consultation with the health care provider helps assess the significance because contamination is more likely. In select situations, blood cultures or cultures from other sites may help determine the significance of the isolate. Although rarely associated with UTIs, mycobacteria have added significance in patients with human immunodeficiency virus (HIV) infection or those who are otherwise immunosuppressed.

Fungi

Candiduria is rare in healthy adults, with one 10-year retrospective study revealing up to a 0.75% rate; however, candiduria is more commonly seen in hospitalized patients. Up to 10% of patients in tertiary care facilities have *Candida* in their urine. Over the past few decades, healthcare-associated candidal UTIs have increased, with fluconazole resistance, a

drug commonly used to treat *Candida*, also increasing. *Candida albicans* is the most clinically significant species. Of particular concern is the globally emerging *Candida auris*. This yeast is highly drug resistant and virulent with a mortality rate up to 60% in a variety of infections. *Candida dubliniensis* is a rare isolate most often seen in patients who are immunocompromised. Predisposing factors for *Candida* UTI include diabetes mellitus, antimicrobial and corticosteroid therapy, incidence of urinary instrumentation, female sex, and disturbance of urine flow. Most candidal UTIs are acquired via the ascending route.

Other yeasts that can be isolated in urine cultures include *Cryptococcus* spp. and dimorphic fungi. These are very rare occurrences and generally present in a manner that would involve other types of cultures, such as CSF or tissue cultures, or other diagnostics tests to supplement the finding. The isolation of other pathogenic fungi, such as *Blastomyces dermatitidis*, *Coccidioides immitis*, and *Histoplasma capsulatum*, in urine is highly significant and indicative of disseminated infection regardless of colony count.

Most yeasts are evident in culture within 2 to 5 days; however, urine cultures are generally held for no more than 3 days. If the health care provider suspects fungal involvement, it is better to order a fungal culture that may be held for up to 8 weeks rather than a standard bacterial urine culture. Consultation between laboratory scientists and the health care provider are best in these cases.

On agar media, early colonies of *C. albicans* can resemble colonies of coagulase-negative staphylococci, requiring a review of Gram-stained smears to avoid misidentification. Because *Candida* spp. often are recovered from hospitalized patients with indwelling catheters, incorrect identification as bacteria, rather than a yeast, results in a susceptibility report indicating broad antimicrobial resistance and can grossly affect patient care. A wet mount preparation examined under $\times 10$ magnification also can provide a rapid identification. Older colonies, 48 hours or more, may exhibit “feet” or “starbursts” around the colonies, which is indicative of *Candida* spp. A germ tube assay for the presence or absence of pseudo-hyphal elements can help speciate the *Candida* spp. into *C. albicans/dubliniensis* or others. *C. auris* is thought to be misidentified by traditional methods. Matrix-assisted laser desorption/ionization-time-of-flight (MALDI-TOF) mass spectrometry is likely the most accurate identification method.

Although findings of candiduria may not require antifungal therapy, particularly in catheterized patients, properly collected urine specimens yielding *Candida* spp. should be considered abnormal. Candiduria may be an indication of bladder or renal parenchymal infection, urinary tract fungus ball, or disseminated candidiasis.

Optimal management of candiduria is still debated. A paucity of data regarding the efficacy of antifungal agents in the urinary system exists. One study involving hospitalized patients with candiduria (asymptomatic or minimally symptomatic) showed that the antifungal agent fluconazole was effective for short-term eradication, but long-term eradication rates were disappointing. Experience has shown that removal of catheters is effective in eliminating candiduria in catheterized patients.

Case check 37.3

Common causative agents of UTIs include coagulase-negative staphylococci, *E. coli*, *Klebsiella*, other Enterobacterales, and enterococci. *Pseudomonas* spp. and *Candida* spp. are also seen, especially in healthcare- or catheter-associated UTIs.

Other agents of urinary tract infections

Anaerobes, common microbiota in the urethra, are not usually responsible for UTIs but may be significant when isolated from suprapubic aspirates. *C. trachomatis* and *N. gonorrhoeae* can cause urethritis, cystitis, and prostatitis. This is particularly an issue with women, in whom it is clinically difficult to distinguish between urethritis and **cervicitis**. Recently, *Mycoplasma* and *Ureaplasma* organisms have been associated with UTIs, particularly in neonates from lower socioeconomic groups and in individuals with HIV infection.

With recent advances in total laboratory automation (TLA), the speed at which urine cultures are inoculated to media is faster than in traditional manual setups. This has enabled microbiology laboratories to recover urinary pathogens that otherwise may have perished before inoculation was performed. From this and the combination of more accurate identifications attributed to MALDI-TOF technology, more isolates of *Alloscardivia omnicolens*, *Actinomyces* spp., and *Actinotignum schaalii* (formerly *Actinobaculum schaalii*) have been isolated with enough consistency to warrant these as emerging or novel pathogens.

Identification of *Gardnerella vaginalis* in urine commonly reflects vaginal contamination. However, this organism is also gaining credibility as an emerging urinary tract pathogen as repeated reports emerge in which this microbe is the primary isolate. *G. vaginalis* is typically cultured in older adult women, suggesting it may be associated with a postmenopausal change. Certain organisms, particularly *Salmonella* spp., are involved with multiple organ systems; these may be part of a primary disease or can arise secondarily. To a lesser extent, species of *Enterobacter*, *Morganella*, *Serratia*, *Hafnia*, *Kluyvera*, *Acinetobacter*, *Lactobacillus*, and *Streptococcus* have all been implicated in UTI.

Viral agents, especially adenovirus and herpes simplex virus, have also been associated with cystitis and should be sought when the clinical situation warrants. Although

Table 37.5 Most common causative agents of urinary tract infections associated with frequent clinical presentation (disease syndromes)

Clinical presentation	Common causative agents
Upper urinary tract infections	
Acute pyelonephritis	Enterobacterales <i>Staphylococcus aureus</i>
Subclinical pyelonephritis	Coagulase-negative staphylococci <i>Candida</i> spp. <i>Mycobacterium</i> spp. <i>Mycoplasma hominis</i>
Lower urinary tract infections	
Acute bacterial cystitis	<i>Escherichia coli</i> <i>Klebsiella</i> spp. Other members of the Enterobacterales Enterococci Coagulase-negative staphylococci
Urethritis	
Acute urethral syndrome	<i>Chlamydia trachomatis</i> <i>Neisseria gonorrhoeae</i> <i>Mycoplasma genitalium</i> <i>Ureaplasma urealyticum</i>
Other infections	
Gonococcal urethritis	<i>N. gonorrhoeae</i>
Chlamydial urethritis	<i>C. trachomatis</i>
Vaginitis	<i>Gardnerella vaginalis</i> and <i>Mobiluncus</i>
Prostatitis	Resembles those of acute bacterial cystitis
Catheter-associated (hospital-associated) urinary tract infection	<i>E. coli</i> <i>Klebsiella</i> spp. <i>Proteus mirabilis</i> <i>Pseudomonas</i> spp. <i>Candida</i> spp.
Chronic or recurrent (inpatient/outpatient) urinary tract infection	<i>E. coli</i>

exceedingly rare outside central Africa, *Schistosoma haematobium* is the only parasite known to be detected in urine. The eggs tend to lodge in the urinary tract causing chronic infections and increased risk of bladder cancer. Table 37.5 presents organisms associated with UTIs, listing the uropathogens usually associated with a particular clinical presentation or disease syndrome.

Laboratory diagnosis

Significance of colony counts: historic background

The urinary tract above the urethra in normal healthy individuals is sterile, as is urine, unlike the urethra, which is colonized with perineal microbiota. In women, vaginal biota can contaminate the urine, but many of the organisms that colonize the vagina are also implicated in UTIs. Therefore it

could be difficult to know whether growth in urine cultures is indicative of infection or contamination.

For decades, quantitative urine culture determination has been considered one of the more straightforward and simple laboratory tests to diagnose UTIs. It was accepted that a finding of 10^5 CFU/mL or more symbolized infection. In his 1956 classic study, Kass showed a clear distinction between the number of bacteria in the urine of asymptomatic or symptomatic women with pyelonephritis and those who were uninfected. When infected, 95% had colony counts higher than 10^5 CFU/mL. All specimens were collected by catheterization (not voided), most asymptomatic women had counts below 10^3 CFU/mL, and the prevalence of infection was only 6%. With this low prevalence rate, the number of false-positive results would be high and hence the 10^5 CFU/mL positive infection cutoff point. The sensitivity was only 51% for women with clinical pyelonephritis who had colony counts above 10^5 CFU/mL.

In the 1960s and 1970s, additional studies began to challenge Kass's original work. Several investigators showed that among symptomatic women with acute lower UTIs (urethra, bladder, or both), 29% to 45% had colony counts lower than 10^5 CFU/mL by suprapubic aspiration. These women had **dysuria** and **pyuria**, yet unexpectedly negative cultures by the traditional Kass-based criterion (e.g., more than 10^5 CFU/mL signifying infection). In 1980, **acute urethral syndrome**, or urethritis, was more clearly defined as one of three causes of acute dysuria with pyuria. The other causes were vaginitis and cystitis. The causative organisms included classic coliforms (rapidly growing, lactose-fermenting, gram-negative bacilli), such as *E. coli*, and *S. saprophyticus* at colony counts above 10^3 but below 10^5 CFU/mL. Simultaneously implicated in sexually active women were the emerging nongonococcal urethritis pathogens *C. trachomatis* and *U. urealyticum*. Thus in women with UTIs, as many as 50% had urethral syndrome—not cystitis—and had negative culture results using traditional laboratory methods.

In 1982, Stamm et al. reexamined the diagnostic criteria for women with acute symptomatic lower UTIs. In contrast with Kass's classic work, Stamm's study included coliforms at a threshold above 10^2 CFU/mL, which provided a sensitivity of 95% and a specificity of 85%. The presence of pyuria in uncentrifuged urine specimens was a sensitive adjunct. The prevalence of coliform infections was 36% in women evaluated by Stamm compared with Kass's 6%. Because of the higher infection prevalence, the positive predictive value (PPV) of infection also increases, and the number of false-positive results decreases. Stamm used a low cutoff of 10^2 CFU/mL to differentiate infection from contamination.

In the late 1980s, because of the emerging significance of pyuria, investigators reevaluated the accuracy of the classic urinary sediment microscopic examination often performed as part of a urinalysis. There was concurrence that microscopic urine screening for detection of UTI was inherently inaccurate, not reproducible, and had no direct correlation with clinically proven UTIs, so microscopic examination of urine specimens should be reserved for the detection of casts and crystals. Furthermore, urinalysis assessment of WBCs could not be correlated with the actual leukocyte excretion rate (WBCs per microliter) measured by hemocytometer chamber count. When clinical studies using the latter method

of determining pyuria were reviewed, the following conclusions emerged:

- A urine leukocyte count of $10/\mu\text{L}$ or higher occurs in less than 1% of asymptomatic patients without bacteriuria but in more than 96% of symptomatic men and women with significant bacteriuria.
- Most symptomatic women with pyuria but without significant bacteriuria have UTIs with bacterial uropathogens present in colony counts from 10^2 to 10^5 CFU/mL or have infections with *C. trachomatis* or *U. urealyticum*.
- Women with ASB with pyuria probably should be categorized as having true infection, whereas women with ASB with no pyuria are categorized as having transient self-limited bladder colonization.
- Most patients with catheter-associated bacteriuria also have pyuria—hence infection.
- Simultaneously, an impregnated paper strip that measured urine leukocyte esterase was introduced and found to correlate well with hemocytometer chamber counts. The leukocyte esterase test is inexpensive and quick (1 minute) and requires no technical skills or equipment.

The significance of these conclusions was not readily apparent. Until recently, the colony count was regarded as the gold standard for determining whether a patient had a real and treatable UTI. However, the urine bacterial colony count cannot stand alone as a single criterion when evaluating a patient for the presence or absence of UTI. Urine culture is requested not only in connection with acute UTI symptoms but also in the absence of specific symptoms; as a test of cure; to detect ASB in pregnant women; and to evaluate patients for bacteremia, fever, or both.

The criteria that determine whether a UTI is present must include the presence or absence of symptoms, predisposing factors, patient population, and type of organism(s) isolated. Therefore the outcome of a urine culture must be evaluated along with other laboratory and clinical data. Attempts to attach significance to the colony count should be restricted to the original patient population in which that significance was established, that is, asymptomatic individuals with pyelonephritis.

Specimen collection and transport

Preventing contamination by normal vaginal, perianal, and interior urethral biota is the most important consideration when collecting a clinically relevant urine specimen. The microbiology laboratory will determine the significance of an isolate based on the total number and types of colonies present. The colony count is also useful for the health care provider who may want to determine the primary organism present and the role of treatment. Therefore all necessary precautions should be taken to ensure that the colony count represents the number of organisms present in urine when the specimen was collected and not contaminants.

Urine samples should arrive in the laboratory at room temperature, and culture plates should be inoculated within 2 hours of collection unless boric acid has been added to the urine as a preservative. Specimens can be stored refrigerated for up to 24 hours. When a specimen arrives at the laboratory, it must be labeled as to location or timing, and this information must accompany the results for proper interpretation. It

is incumbent on laboratory directors to define specific criteria for collection and transport and, within their realm of responsibility, ensure that these protocols are followed. Culture media and pathogen reporting can vary depending on the source of the urine.

Voided midstream specimen collection

A voided midstream collection, also known as a *clean catch*, is the most commonly used method in clinical practice. The urine is contaminated with bacteria from the urethra unless the first portion of the voided specimen is discarded, hence midstream. Patients who self-collect clean-catch midstream urines must be instructed to use an antimicrobial wipe before collection and, for women, to spread the outer labia to ensure that the urine stream does not include skin biota. Voided urine collection kits should contain instructions for the patient on proper specimen procurement, and instructions should be provided both orally and in print. Patient education should be part of the specimen processing because proper collection has a considerable influence on the result of subsequent laboratory procedures. It has also been reported that diagrams showing the way a specimen should be collected are much more easily understood by the patient compared with written instructions.

Catheterized specimen collection

Catheterized specimen collection, an invasive technique, reduces the risk of contamination of urine by the urethral biota; however, because the catheter passes through the urethra, some contamination can occur. Before urine is collected with a single straight catheter, the urethral opening or vaginal vault is cleansed with a soap solution and rinsed with sterile water. The initial urine flow is discarded because it may contain organisms acquired as the catheter passed through the urethra.

Specimens may also be collected from an existing indwelling urinary catheter by cleaning the catheter collection port with an alcohol pad and puncturing it directly with a needle and syringe. The specimen should never be collected from the Foley drainage bag or output line itself. The longer the patient has the indwelling catheter in place, the more likely the urine sample may be contaminated from biofilms that grow on the walls of the catheter. For this reason, urine cultures from indwelling catheters are best obtained after the catheter is inserted and no more than 3 days postinsertion.

Samples obtained from an ileoconduit are collected from the stomal opening after the area has been swabbed with an alcohol wipe. The urine on the external appliance is never used for culture because, like urine in the drainage bag in patients with indwelling catheters, it is often contaminated. The bacteriologic results of urine specimens collected by cystoscopy (bilateral urethral catheterization) or by bladder washout are used to localize the infection to the upper or lower urinary tract and, in the former case, to the left or right kidney. Specimens obtained by straight catheterization, bilateral urethral catheterization, or bladder washout or from an ileoconduit may be submitted in a tube or broth unless an assessment of pyuria is necessary.

Suprapubic aspiration

Suprapubic aspiration is the definitive method for collecting uncontaminated specimens. Generally, any organism isolated

from these specimens is considered clinically significant; however, this may not be correct because transient colonization of the bladder can occur. Suprapubic aspirations are collected primarily from infants and patients in whom the interpretation of the results of voided specimens is difficult for various reasons.

Alternatively, in infants and young pediatric patients, urine collections are occasionally submitted in a pediatric urine collection bag in which a sterile bag with an opening is adhered to the cleansed genital region of the child. Urine collected via this manner is acceptable for urinalysis, but the utility for microbial culture remains uncertain. Should the laboratory director decide to accept pediatric urine bags as a source, they should consider placing a comment on the final report as the contamination rate in bagged specimens is >50% compared with when a straight catheter sample is obtained. Suprapubic aspiration of urine specimens is the only suitable method to obtain an anaerobic culture. Following skin antisepsis, urine is collected from a full bladder by using a needle and syringe.

Other considerations

In addition to the way the specimen is collected, other parameters can have an impact on the suitability of the specimen and interpretation of culture results.

Urine volume

The volume of urine received is rarely a problem for routine bacteriologic culture. Detection of significant pyuria by sediment examination requires at least 10mL of specimen. Alternative methods of pyuria detection may be needed when smaller volumes are received. At least 20mL of urine may be required to recover mycobacteria or fungi. If these agents are strongly suspected and previous specimens of lesser volume have tested negative, a single, early-morning collection of at least 20 to 40mL should be obtained for culture. However, 24-hour collections for urine specimens in microbiology are unacceptable.

Number of specimens and timing of collection

The number of specimens and the timing of urine collection depend on the patient's clinical state and collection method used. A single, clean-catch, voided specimen or single specimen obtained by catheterization in a symptomatic patient is usually sufficient in the setting of pyuria and a culture revealing a uropathogen. In symptomatic patients, antimicrobial therapy is often instituted immediately after urine collection and is not withheld while waiting to procure subsequent specimens. For purposes of optimal yield, particularly for mycobacteria, it has been recommended that only first-morning specimens be processed; if such specimens are not available, the urine should be allowed to incubate in the bladder for as long as possible (at least 4 hours) before collection to increase the bacterial density and therefore culture sensitivity. *S. haematobium* parasite eggs are shed based on the circadian rhythm of their human host and are present at the greatest concentration at noon. Therefore urine for detection of *S. haematobium* is best collected around midday and adjusted if the patient has recently returned from another global time zone.

In the absence of symptoms, a single, first-morning voided urine specimen from a pregnant woman is sufficient to detect ASB. In this case, one or two more first-morning specimens may be collected on separate days to demonstrate the significance of the isolates. Because quantitation is necessary for

the diagnosis of ASB and because an asymptomatic condition does not require immediate therapeutic intervention, these specimens should be limited to first-morning collections. Urine specimens from other asymptomatic patient populations, except those demonstrating significant pyuria, cannot be reliably interpreted.

Additives

Additives to urine specimens are designed primarily to preserve the bacterial density present at collection. These additives maintain the original colony count during ambient temperature transport until quantitative cultures can be accomplished, obviating the need for refrigerated transportation, which can be destructive to certain fastidious pathogens such as *N. gonorrhoeae*.

Sodium borate (boric acid) maintains the sample integrity for up to 48 hours after collection at room temperature, preventing overgrowth of nonpathogenic biota without impairing growth of existing pathogens. Liquid preservatives have been associated with dilution errors and decreased recovery of organisms at 24 and 48 hours. Lyophilized preservation is less inhibitory but requires a urine volume of at least 3 mL to avoid pathogen inhibition. However, lyophilization requires instrumentation that is not routinely available to most provider offices and hospitals.

The effects of preservatives on the detection of pyuria have not been adequately determined. Regardless of the preservative used, the maximum time from collection to processing should not exceed 24 hours. In addition, the effect of preservatives on selected manual and automated TLA methods (see later) has not been extensively evaluated. The importance of identifying pyuria in many cases and the lack of evidence that urine preservatives allow an accurate leukocyte count after 2 hours argue against the use of preservatives for specimens from symptomatic patients.

Microbial detection

Specimen screening: rapid nonculture methods

Often, urinalysis of clean-catch specimens is a multistep tiered algorithm that begins with a urinalysis dipstick for the presence of nitrites, blood, and/or leukocyte esterase, and urine pH. Leukocyte esterase and nitrite tests have low sensitivity, especially when low numbers of bacteria are present. If there are indications of infection from the dipstick results, a microscopic examination of the urine is performed. In a microscopic examination, the presence of bacteria, yeast, erythrocytes, and leukocytes, as well as casts and urine crystals can determine if further investigation is necessary. This method can also reveal the presence or absence of bacteria or fungi. The presence of struvite crystals, caused by the formation of magnesium ammonium phosphate crystals at basic urine pH, may be indicative of infections caused by *Proteus* or *Klebsiella* species, which produce urease and alter the normal pH of urine.

Dipstick urinalysis and microscopic examination should be reported within 2 hours after collection of a urine specimen. Based on the results of the microscopic examination, microbial cultures could be indicated. Although this is a

common algorithm, the specific parameters causing reflex to the next diagnostic assay varies among laboratories. Should the patient's situation dictate a deviation from the algorithm, many laboratories also give the health care provider discretion to independently order each assay. Because timing is important for interpretation of the preliminary and final reports, the collection time, time received by the laboratory, and time to final report should be disclosed. In addition to providing important information to the health care provider early in the diagnostic analysis, a tiered algorithm has shown to decrease the frequency of negative urine cultures, decrease workload in the microbiology laboratory, and improve antimicrobial stewardship by de-escalating antimicrobial use.

Many providers will initiate treatment based on the knowledge of which organisms and their antimicrobial susceptibility patterns (cumulative antibiograms) are circulating in the local community. Each laboratory strives to publish an antibiogram, which is a summary of the number, sources, and antimicrobial profiles of pathogen isolates each year. As preliminary reports are updated, the treatment can be further refined.

Several key points should be considered when using screening methods:

- Screening methods capable of detecting bacterial densities of 10^5 CFU/mL or higher are appropriate for the detection of ASB in pregnant women.
- False-positive results occur more often with methods that test for multiple parameters (e.g., bacteria and WBC count).
- Methods detecting significant pyuria and bacteriuria with sensitivities of 50 to 100 leukocytes/ μ L and 10^2 CFU/mL may be appropriate for screening voided urine specimens or those from indwelling urinary catheters in symptomatic patients.
- Screening methods for urine collected by invasive means should be considered for microbiology culture whether or not a tiered algorithm is used. This includes straight catheterization, cystoscopy, suprapubic aspiration, or bladder washout specimens.

Manual urine screening methods

Detection of bacteria when pyelonephritis is suspected

Microscopic examination of Gram-stained smears of urine samples is a debatable practice because of low sensitivity. Also, if staining is performed, it is not recommended to report the microscopic morphology of the organisms because of the low specificity and the inability to distinguish viable from nonviable organism and pathogens from contaminants. Gram-stained smears can reveal the presence and absence of bacteria or yeast, but they generally cannot distinguish between monomicrobial or polymicrobial infections, especially if the morphology of two or more pathogens is the same.

When microscopic analysis is performed, urine concentration and sediment analysis or cytospin technology is best. The presence of one or more bacterial cells per oil immersion field in at least five fields in a smear of uncentrifuged urine correlates with more than 10^5 CFU/mL. If the uncentrifuged preparation is negative, the sediment preparation for leukocyte examination should be stained. Bacterial cells seen in this preparation indicate a density of fewer than 10^5 organisms/mL and, in the

Table 37.6 Manual screening methods, principles of assay, and threshold of detection for urinary tract infections

Screens	Principle	Reported threshold of detection (CFU/mL)
Manual		
Microscopy Direct, uncentrifuged or centrifuged (cytospin)	Recognition of organism morphotypes and Gram stain	1-2 organism/OIF = 10^5
Chemical		
Enzymatic dipstick		
Nitrate reductase (Griess test)	Gram-negative bacteria reduce nitrates to nitrites	
WBC leukocyte esterase	Measures presence of WBC enzyme	Equivalent to 5 WBC/hpf
Chemstrip LN	Combination testing of nitrate and esterase assays	$>10^4$ – 10^5
Enzyme tube		
Uriscreen ^a	Measures catalase present in bacteria and somatic cells	$<10^4$ – 10^5

presence of clinical findings of acute pyelonephritis, may suggest urinary obstruction or perinephric abscess. The presence of bacteria or fungi assists in the selection of an appropriate antimicrobial therapy. Table 37.6 lists various manual screening methods useful for detecting bacteria and leukocytes in urine.

Detection of pyuria

Pyuria often indicates urethritis, cystitis, or pyelonephritis. Detection of leukocytes may be performed by a urine dipstick or microscopic examination of a wet mount of a urinary sediment. At least five fields should be examined, and each leukocyte seen per high-power field ($\times 400$) represents approximately 5 to 10 cells per microliter of urine. In this way, 5 to 10 leukocytes per high-power field in the sediment is the upper limit of normal, representing at least 50,000 cells/mL. If a more precise method is required for cell quantitation, cells in unconcentrated urine can be counted using a hemocytometer chamber. The presence of more than 8 leukocytes/ μ L indicates significant pyuria.

Case check 37.4

Urinalysis and microscopic examination can aid in the diagnosis of UTIs by detecting leukocyte esterase and the number of leukocytes, which can add to the significance of the bacterial colony count. The presence of bacteriuria and pyuria usually indicate infection. Microscopic examination can help with the preliminary detection of infectious etiologies to guide early therapy.

Detection of fungi and mycobacteria

First morning specimens are recommended, and large volumes (10 mL to 50 mL) give best results. Urine should be centrifuged at $2000 \times g$ for 10 minutes, especially when deep mycoses are suspected. Yeast cells can usually be readily identified by microscopic analysis, but the cells of other fungi may be difficult to discern because of their varied size and unique forms. For these reasons, an examination of a wet mount

should be scanned at $100\times$ and $400\times$ magnifications before using $1000\times$. If fungi are suspected clinically or from microscopic analysis, a smear of the sediment can be stained with calcofluor white and examined using fluorescent microscopy. This stain binds to chitin present in the cell walls of fungi and makes visualization easier. Because calcofluor white also binds to cellulose, which chemically resembles chitin, cotton swabs should not be used because they too will fluoresce. Quantitative colony counts, as performed for bacteria, are not useful for fungi. In pyelonephritis studies from the 1970s, researchers did not find a correlation between infections confirmed by renal biopsy and colony counts.

Automated urine screening methods

Table 37.7 summarizes various automated screening methods used for bacterial detection in urine samples. Such systems may be expensive, frequently require batching of specimens (therefore causing time delays), and have not been adequately evaluated for their efficacy in detecting low-grade bacteriuria and funguria.

Molecular screening and identification methods

Molecular methods have the advantage of providing faster microbial identification than traditional culture techniques but are incapable of discerning organism viability. This technique shows promise with identification of the most common infectious organisms, such as *E. coli*, but is not useful for uncommon infectious agents. Furthermore, predicting antimicrobial susceptibility by polymerase chain reaction (PCR) can only account for resistance mechanisms that are genetically based and previously identified. Mechanisms such as chemical changes to the cellular outer membrane layer would be undetected by most molecular techniques and provide a discrepancy for antimicrobial susceptibility between PCR and culture techniques. Another drawback to molecular analysis is if multiple pathogens are detected, it is difficult to

Table 37.7 Automated screening methods, principle of assay, and threshold of detection for urinary tract infections

Automated method	Principle	Threshold of detection (CFU/mL)
Bioluminescence	Detects bacterial ATP using enzymatic bioluminescent reaction of ATP with luciferin and luciferase	$>10^4$ – 10^5
Photometry	If a significant number of organisms are present in the urine specimen, they will grow in the medium to a concentration detectable by photometry (i.e., light scattering)	$>10^4$ – 10^5
Flow cytometry	Detects and quantifies bacteria, WBCs, and RBCs with color-coded scatter diagrams	$>10^3$
PCR	Detects specific nucleic acid sequences that were selected to be unique to the organism or groups of organisms common in UTIs	Varies depending on targets used and assay specifications

ATP, Adenosine triphosphate; CFU, colony-forming unit; PCR, polymerase chain reaction; RBC, red blood cell; UTI, urinary tract infection; WBC, white blood cell.

determine if this is a true polymicrobial infection or contamination. Only culture or quantitation of each pathogen target relative to one another can determine this.

Rejection criteria

It is imperative that the laboratory establishes, in concert with various medical services, the criteria for obtaining optimal specimens. Specimens may be rejected because of an inadequate or inappropriate method of collection or transport. These criteria demand strict adherence to guidelines for the collection and transport of specimens. If the specimen does not meet these tailored guidelines for each institution, it is incumbent on the laboratory to inform (as soon as possible) the service, health care provider, or both about the inadequacy of the specimen and the fact that the specimen will not be processed. Antimicrobial therapy may not have been initiated, and a better specimen might still be collected. Samples to be rejected include 24-hour urine specimens and Foley catheter tips.

Culture for causative agents of urinary tract infections

Methods for culture differ among different laboratories. Generally, routine urine culture should include plating onto one gram-negative selective medium (e.g., MacConkey or eosin–methylene blue agar) and one nonselective medium (sheep blood agar). Columbia colistin–nalidixic acid blood agar can inhibit gram-negative rods and allow gram-positive organisms to grow, but a comparison of the gram-negative differential to nonselective plate can generally yield the same information without the need for an additional medium. Chromogenic agar can be useful to identify and distinguish organisms in mixed cultures. These include CPS ID3 (bioMérieux, Durham, NC), Remel Spectra UTI chromogenic medium (Thermo Fisher Scientific, Waltham, MA), and BBL CHROMagar Orientation (BD Diagnostic Systems, Sparks, MD).

Calibrated loops of 0.001 mL (1 μ L) or 0.01 mL should be used to quantify the number of bacteria present in the urine sample. Use of 0.01 mL can detect as few as 10^2 CFUs. The urine specimen should be mixed thoroughly, and the calibrated loop should be inserted vertically as a more horizontal position can increase the volume beyond calibration. The loop should be redipped for each plate inoculated.

Streaking one plate for quantitation using a T-streak method and another for isolation using a traditional quadrant streak may help quantitate and isolate colonies for further work and lower the possibility of subculture to additional media before identification and antimicrobial susceptibility testing is required.

Plates should be incubated for at least 16 hours, but preferably for 18 to 24 hours at 35° C. The culture protocol should be able to detect the most common pathogens, such as Enterobacterales, and species of *Staphylococcus*, *Pseudomonas*, and *Enterococcus*. Antimicrobial susceptibility testing should be performed on organisms with significant colony counts or from symptomatic patients who have three or fewer morphologically distinct colony types. More than four colony types, especially when they are similar in abundance, suggests contamination and should be reported as such.

Asymptomatic bacteriuria

If the patient is asymptomatic, immediate antimicrobial therapy is not necessary unless the patient is pregnant or undergoing GU surgery. Identification and susceptibility testing of isolates can be achieved by conventional or automated methods. The colony count should accompany any positive culture result to indicate the diagnosis of ASB. Because the organisms most frequently identified include *E. coli* and other rapidly growing members of the order Enterobacterales, 24 hours of incubation at 35° C is sufficient.

Pyelonephritis

Urine specimens submitted from patients suspected of having pyelonephritis generally contain high colony counts of bacteria. Microscopic examination of urine for leukocytes and bacteria might quickly provide therapeutically useful information. Because the antimicrobial susceptibilities of the responsible organisms are variable and unpredictable, culture should be designed for optimal recovery and antimicrobial susceptibility testing.

Lower urinary tract infections

Specimens from patients with symptoms of L-UTI should be processed in the same manner as for suspected cases of pyelonephritis. If there is significant pyuria in a patient who is symptomatic and no recognized urinary pathogen is

detected, then *C. trachomatis*, *Mycoplasma* spp., *U. urealyticum*, *N. gonorrhoeae*, or *M. tuberculosis* should be suspected. For gonococcus and chlamydia, first-morning voided urine (not midstream urine) is recommended. Urine PCR is available to detect *N. gonorrhoeae* and *C. trachomatis*.

Suprapubic aspirates

Suprapubic aspirates might contain bacteria likely to be present in low numbers and may include anaerobic species. Such specimens should be routinely inoculated on a blood agar plate, MAC agar plate, and trypticase soy broth (TSB) for up to 48 hours. For recovery of *G. vaginalis*, chocolate agar is acceptable. If growth is observed in the lower half or less of the TSB tube and little or no growth is present on the aerobic plates, an anaerobe may be considered. Anaerobic bacteria are recovered in approximately 1% of cases and therefore need only be sought after consultation.

Catheterized specimens

Urine specimens obtained by straight catheterization, bilateral ureteral catheterization, bladder washout, or ileoconduits require inoculation of agar plates for maximum recovery.

Case check 37.5

Urine can be collected by several methods. The simplest is voided midstream, which is also most likely to be contaminated. Catheterized specimen collection is more invasive, but specimens are less likely to be contaminated. The definitive method to obtain an uncontaminated urine specimen is suprapubic aspiration, which is also the most invasive.

Prostatic secretions

The causative agent of acute prostatitis is usually recovered from catheterized specimens, which should be cultured in the same manner as for specimens from symptomatic male patients. In cases of chronic prostatitis, prostatic secretions are submitted as well as urethral urine and midstream-voided urine specimens obtained before and after prostatic massage. Quantitative cultures are necessary for proper interpretation.

Historically, yeasts have been detected within 24 hours, but certain species may need 48 hours of incubation. When isolated, the numbers of yeasts should be reported. Low colony counts may be just as significant as high colony counts.

Interpretation of results

Routine workup of isolates and susceptibility testing must be tailored according to the patient and the specimen type submitted. Fig. 37.4 shows a flow diagram that considers three features that should be considered in all UTIs:

- Colony count of a pure or predominant organism
- Measurement of pyuria
- Presence or absence of symptoms (e.g., dysuria and urinary frequency)

It is important to recognize, however, that no one scheme fits all situations. Fig. 37.4 is organized into a cascade scheme using a dichotomous key, which allows for 12 clinical categories, depending on knowledge of symptoms and health care provider input. Historically, most guidelines suggested that laboratory evaluation and culture setup should depend on previous knowledge of symptoms. Because this is often unrealistic, the schema presented allows the final differentiation to be made by the health care provider, based on his or her knowledge of the patient's signs and symptoms. Furthermore, if the patient is receiving antimicrobial therapy, microscopic examination, WBC analysis, and culture results might not agree. Finally, quantitation of organisms and WBCs by urinalysis of a centrifuged specimen has no comparative value for the leukocyte esterase and bacteria measurement in microbiological study, which is performed routinely on a noncentrifuged urine specimen. Fig. 37.4 addresses acute urethral syndrome and the recognition that cystitis and urethritis are clinically difficult to differentiate, particularly in female patients. It is imperative that health care providers recognize that routine urine cultures do not include the isolation and identification of *C. trachomatis*, *N. gonorrhoeae*, or *U. urealyticum*.

Given the high propensity of negative cultures sent to the laboratory ($\approx 50\%$), reevaluation of the patient with a negative culture result may require consideration of an STI. Table 37.8 lists guidelines for the interpretation of urine culture results and suggests the subsequent workup. In summary, these guidelines recommend the following, keeping in mind that cost-effective strategies might define different algorithms for inpatient and outpatient cases:

- Multiple uropathogens (i.e., three or more) in a specimen indicates probable contamination.
- One or two significant uropathogens present ($\geq 10^5$ CFU/mL) should be routinely identified. Susceptibility tests should be performed for inpatients. Outpatient cases may use a different algorithm that does not call routinely for susceptibility tests; rather, it emphasizes empiric selection based on antibiograms. However, some centers may perform susceptibility testing on all urine culture isolates in the setting of increasing drug resistance.
- One or two uropathogens present in small numbers ($\geq 10^2$ to $<10^5$ CFU/mL) should be routinely identified if the clinical situation warrants, such as in acute urethral syndrome or cases of previous antimicrobial therapy.

Susceptibility reporting

With the growing number of emerging uropathogens and simultaneous increase in newer antimicrobial agents, it is mandatory that laboratories use standardized methods and report only appropriate agents for treating UTIs. Antimicrobial agents approved by the U.S. Food and Drug Administration (FDA) for routine testing and reporting by clinical microbiology laboratories for urinary tract isolates are listed as group U supplemental for urine only in the Clinical and Laboratory Standards Institute (CLSI) M100 document, which is updated annually. The CLSI document provides interpretations of

^aLeukocyte esterase (+); equivalent to 5 WBCs/hpf.

^bClinical dysuria and frequency.

^cIf patient is receiving antimicrobial treatment, the result of the Gram stain, WBC analysis, and culture may not agree.

^dQuantitation of organisms and WBCs by urinalysis of a centrifuged specimen is of no comparative value for the measurement of leukocyte esterase and bacteria done by microbiological study, which is performed routinely on a noncentrifuged specimen.

^eInterpretation for indwelling catheter has not been established.

^fPlates held for 72 hours for consultation.

Fig. 37.4 Interpretation of urine culture results using an algorithm based on bacterial colony count, pyuria, and symptoms. CMV, Cytomegalovirus; hpf, high-power field; HSV, herpes simplex virus; WBC, white blood cell.

antimicrobial susceptibilities based on both the minimum inhibitory concentration (MIC) method and the disk diffusion methods. Because the interpretation of MIC or disk diffusion results can vary based on additional scientific and case study analysis, laboratory directors must make yearly decisions about whether they will update the CLSI standard or retain the FDA-approved values. Refer to [Chapter 13](#) for more information on antimicrobial susceptibility testing. Several laboratories have tailored susceptibility testing according to the needs of the clinical setting: outpatient versus inpatient, pediatric versus adult, and ICU versus non-ICU. It is important to remember that attainable antimicrobial blood levels and urine levels are often different; this will have an impact on the

interpretation of some semi-quantitative susceptibility results or the MIC of inhibitory antimicrobial agents.

Urinary tract infection antibiograms

Historically, one of the primary functions of the clinical microbiology laboratory has been to measure antimicrobial resistance trends. This was generally accomplished by using an annual antibiogram that established cumulative percentage susceptibilities for selected UTI bacteria–antimicrobial combinations. Today, this is even more important and requires focused antibiograms that tailor these historical resistance fingerprints to selected patient locations, inpatient versus

Table 37.8 Guidelines for interpretation of urine culture results and subsequent workup

Significant colony count (CFU/mL) ^a	Symptoms, clinical disease, or patient population ^b	Urine source	Number of organism types isolated	Laboratory workup suggested (inpatient) ^c
$\geq 10^4$ $\geq 10^3$ ^b		CC CA	None	None ^d
$\geq 10^4$	Pediatric	Suprapubic	≤ 2 organisms by anaerobic culture	ID and AST
$\geq 10^4$	Symptomatic female, urethritis	CC	Pure culture	ID and AST
$\geq 10^4$	Symptomatic male, prostatitis	CA CA	≤ 2 organisms Pure culture	ID and AST ID and AST
$\geq 10^4$		Bladder washout		ID and AST
$\geq 10^4$	Cystitis, pyelonephritis	CC	Pure culture Two or three organisms Three organisms	ID and AST Q and SID Q and M or Q and GS

CA, Straight catheterized; CC, clean-catch voided; CFU, colony-forming unit; ID and AST, perform identification and antimicrobial susceptibility testing; Q and GS, quantitate and report Gram stain morphotypes; Q and M, quantitate total amount of bacteria and report as "mixed urethral microbiota"; Q and SID, quantitate and perform sight identification, identification and sensitivity not indicated, hold plates for 72 hours.

^aInoculation of 0.01 mL of urine is required to detect 10^2 CFU/mL, however, at least 10 colonies on the plate are required for significance. Use of a 1- μ L loop means reporting of 10^4 CFU/mL or a 10- μ L loop for reporting of 10^5 CFU/mL or greater colony counts.

^bSee Table 37.1 for a description of clinical diseases, symptoms, and patient population.

^cWorkup required. Any yeast may be quantitated and reported, regardless of number; $>100,000$ needed to identify to species.

^dSee figures and text for suggested comments and educational information helpful to health care providers.

outpatient status, disease type, and patient age. Most importantly, if the laboratory has a large enough volume of isolates to enable reassessment of an antibiogram more frequently than annually, it should be a consideration to help clinicians choose empiric therapy for inpatient and long-term care settings. Outpatient urine isolates often have a stable and predictable pattern.

POINTS TO REMEMBER

- UTIs occur frequently, especially in women; 50% of all women will have a UTI in their lifetime.
- The pathogenesis and course of a UTI depends on the organs involved and the patient's state of health.
- L-UTIs involve the bladder (cystitis), urethra (urethritis), or prostate (prostatitis). Symptoms can include dysuria, hematuria, and changes in urinary frequency.
- U-UTIs involve the kidneys (pyelonephritis) or ureters (ureteritis). Symptoms can include fevers, chills, night sweats, nausea, vomiting, flank pain, and costovertebral angle tenderness.
- Common causative agents of UTIs include coagulase-negative staphylococci, *E. coli*, *Klebsiella* spp., other Enterobacteriales, and enterococci. *Pseudomonas* spp., *Proteus* spp., and *Candida* spp. are also seen, especially in healthcare- or catheter-associated UTIs.
- Urinalysis and culture are important components in the evaluation of UTIs. The presence of bacteriuria and pyuria indicates infection.
- Results of a urinalysis dipstick (i.e., positive leukocyte esterase and nitrites) often will result in a reflex to a urine culture by most clinical laboratories.
- Interpretation of urine cultures depends on several factors including number and types of isolates, colony counts, type of specimen, and patients' history.

LEARNING ASSESSMENT QUESTIONS

1. Which scenario pertaining to urine cultures is most likely to be clinically significant?
 - a. Asymptomatic pregnant female patient with bacteriuria, pyuria, and 10^3 CFU/mL of *E. coli* in a voided urine specimen
 - b. Asymptomatic female patient with bacteriuria, no pyuria, and 10^4 CFU/mL of *E. coli* in a voided urine specimen
 - c. Asymptomatic older adult male patient with 10^5 CFU/mL of *S. epidermidis* and enterococci in a urine sample collected from a Foley catheter
 - d. Symptomatic male patient with 10^5 CFU/mL of *E. coli*, *S. epidermidis*, and *P. mirabilis*
2. Which collection method is most likely to result in urine culture contamination?
 - a. Suprapubic aspirate
 - b. Collection from a urine catheter port after catheter placement
 - c. Clean catch from a male patient
 - d. Urine collected from a Foley bag
3. If a blood culture and urine culture are positive with the same organism, what is the likely route of the urinary tract infection?
 - a. Ascending route
 - b. Lymphatic route
 - c. Hematogenous route
 - d. These are unrelated, and route of infection cannot be connected
4. In which of the following patient populations are you most likely to culture *Proteus* spp. from urine?
 - a. 2-year-old female patient
 - b. 16-year-old sexually active female patient
 - c. 85-year-old catheterized male patient
 - d. Renal transplant patient

5. A culture was inoculated at 10:00 PM, and a newly hired day shift laboratory scientist removed the lid of the culture plate briefly and read the culture at 11:00 AM the next day. This culture was noted as no growth and returned to the incubator for the next day. The following day, an experienced day shift laboratory scientist read the culture as contaminated and reported the result as such. Which of the following is the most likely explanation of why the initial read showed no growth and later appeared contaminated?
 - a. The experienced day shift laboratory scientist misread the plates.
 - b. The first culture was read too early to determine growth status.
 - c. The plates became contaminated because the lid of the culture was removed briefly.
 - d. The newly hired laboratory scientist was not experienced enough to see growth on the plate and erroneously missed the growth.
6. A clean-catch midstream urine sample is received in the clinical laboratory at 6:00 PM. The microbiology laboratory will not be staffed until 7:00 AM the next day. At which temperature should the urine sample be stored?
 - a. 35° C
 - b. 30° C
 - c. 4° C
 - d. -20° C
7. Which of the following is an acceptable practice for urine transportation when a culture will be performed?
 - a. Sending it to the laboratory frozen
 - b. Sending a specimen on ice 3 days after collection
 - c. Sending urine in a sterile collection cup 4 hours after collection at room temperature
 - d. Collecting and immediately transferring the sample to a preservation tube so it will arrive to the laboratory within 24 hours
8. A patient presents to the emergency department with symptoms of a UTI. Your laboratory information system reveals that the patient had a UTI with *E. coli* 3 months earlier. What is the next step to take?
 - a. Do not set up a culture as the health care provider is likely already treating the patient.
 - b. Do not set up a culture and refer the health care provider to the previous urine culture.
 - c. Set up cultures, and if *E. coli* is isolated, consider making a note to the health care provider that previous infection grew the same organism.
 - d. Set up cultures, and if *E. coli* grows again, disregard the result because it is likely a contaminant.
9. Which one of the following organisms is most likely to be a contaminant in a urine culture?
 - a. *Candida albicans*
 - b. *Klebsiella oxytoca*
 - c. *Neisseria gonorrhoeae*
 - d. *Staphylococcus epidermidis*
10. A health care provider must decide on the best antimicrobial agent to treat a patient before the antimicrobial susceptibility test results are available. Which of the following is *not* a useful guide in deciding the empiric therapy?
 - a. Past patient history of infection and treatment
 - b. The least expensive antimicrobial agent in the pharmacy
 - c. Antibigram published each year by the microbiology laboratory
 - d. Understanding of the patient demographics and likely organisms involved
11. How would the urine culture described in the Case in Point be worked up and reported?
12. Compare the route of urinary tract infection presented in the Case in Point versus common gram-negative bacteria.
13. What is the significance of the patient's clinical symptoms and the positive blood culture results?
14. What is the difference between a single-episode UTI and a recurrent UTI?
15. What is the value of a urinalysis algorithm leading to microbial culture?
16. What is the optimal incubation period for routine urine culture?
17. What may occur if routine urine cultures are incubated for longer than the optimal period?
18. What is the definition of a contaminated urine culture?
19. Why is it important for health care providers to reevaluate negative urine culture results on specimens from symptomatic patients?
20. How would your list of potential urinary tract infection isolates differ among the following patients: a young, sexually active female patient; a middle-age male patient; an older adult female patient; and a patient who has had a recent kidney transplant?
21. A patient with diabetes who underwent kidney transplantation 6 weeks ago develops fever, chills, nausea, vomiting, and dysuria. Which laboratory tests should be performed to aid in the diagnosis of this patient's condition?

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Describe the pathogenesis of the following diseases:
 - Urethritis
 - Cervicitis
 - Vulvovaginitis
 - Genital ulcer disease
 - Acquired immunodeficiency syndrome
2. Recognize the common clinical manifestations, complications, and treatment of pelvic inflammatory disease.
3. Discuss how the advent of molecular testing has affected the identification of sexually transmitted infections.
4. Justify the rationale for offering the human papillomavirus vaccine to those between 9 and 26 years of age.
5. Interpret an acute hepatitis panel and testing results specific for hepatitis B and C.
6. Differentiate the signs, symptoms, and causative agents of gonococcal and nongonococcal urethritis.
7. Compare the laboratory testing methods used to presumptively diagnose or confirm a urethral infection.
8. Justify performing screening tests for women who are sexually active but have no signs or symptoms of infection.
9. Identify potential long-term effects of an untreated infection.
10. Compare the signs and symptoms of bacterial, fungal, and parasitic forms of vulvovaginitis.
11. Describe the expected results of diagnostic tests that can be performed by the health care provider to determine the causative agent of vulvovaginitis.

12. Correlate the signs, symptoms, and laboratory tests required to differentiate among various genital ulcerative diseases.
13. Explain the requirement for performing screening and confirmatory tests for syphilis.
14. Interpret the various expected results of laboratory tests to differentiate between active and latent syphilis.
15. Determine the laboratory test results required to diagnose human immunodeficiency virus (HIV) infection (presumptive or confirmed) in an individual.
16. Evaluate the long-term effects of HIV infection on an individual's immune system.
17. Justify the recommended laboratory tests to be performed after HIV infection has been diagnosed in an individual.

KEY TERMS

Acquired immunodeficiency syndrome (AIDS)	Highly active antiretroviral therapy (HAART)
Bacterial vaginosis (BV)	Human immunodeficiency virus (HIV)
Balanitis	Human papillomavirus (HPV)
Cervicitis	Lymphogranuloma venereum (LGV)
Chancere	Molluscum contagiosum
Chancroid	Nongonococcal urethritis (NGU)
Chlamydia	Nontreponemal antibody tests
Condylomata accuminata	Pelvic inflammatory disease (PID)
Condylomata lata	Proctitis
Donovan bodies	Salpingitis
Epididymitis	Syphilis
Genital herpes	Treponemal antibody tests
Gonorrhea	Trichomoniasis
Granuloma inguinale (donovanosis)	Urethritis
Gummas	Vulvovaginal candidiasis
Hepatitis	

Case in point

A 19-year-old college freshman presents to the student health center complaining of a burning sensation when he urinates. After a recent argument with his girlfriend, the patient spent the weekend on a road trip with several friends, where he indulged in a few casual encounters of unprotected sex. A cloudy watery penile discharge is noted. Direct Gram-stained smear demonstrates a moderate number of white blood cells (WBCs), and no organisms are seen. A urethral swab is submitted to the laboratory for molecular testing, and blood is drawn for **human immunodeficiency virus (HIV)** testing. The patient's health care provider questions him about sexual contacts. The student mentions that his girlfriend, who drove him to the health center, is in the waiting room. The girlfriend, in a private interview, reports not having any genital discomfort or dysuria. The couple does not use condoms, but the girlfriend is taking birth control medication. She has not received the **human papilloma-virus (HPV)** vaccine. She does mention that she woke up that morning with a sore throat and has been taking throat lozenges. Inspection of her throat reveals slight redness and irritation. No throat specimen is submitted for testing. Both the patient and his girlfriend are provided with oral antimicrobial agents, and he is encouraged to notify all of his sexual partners.

Issues to consider

After reading the patient's case history, consider:

- The significance of the direct Gram-stained smear findings of the exudate showing a moderate number of WBCs and no organisms seen
- Why the patient should notify all of his sexual partners
- Whether or not the girlfriend could be infected, even though she was found to have no current signs or symptoms
- Which signs and symptoms would be noted for syphilis, chancroid, and herpes
- If an HIV screening test for this patient would be indicated and be of value

Genital infections and sexually transmitted infections (STIs) are caused by organisms normally present in the reproductive tract or introduced from the outside during sexual contact. STIs are spread primarily through intimate person-to-person sexual contact, including vaginal intercourse, oral sex, and anal sex. Several STIs, in particular **acquired immunodeficiency syndrome (AIDS)**, **chlamydia**, and **gonorrhea**, can also be transmitted from mother to child during pregnancy and childbirth. HIV, the causative agent of AIDS, can be transmitted through blood products and tissue transfer. There are more than 30 different sexually transmissible bacteria, viruses, epizoa, fungi, and parasites. Use of the term *sexually transmitted diseases* (STDs) denotes a diverse group of infectious diseases with a wide variety of pathogens and wide-ranging clinical manifestations (Table 38.1). The term

Table 38.1 Sexually transmitted diseases and their causative agents

Disease	Agent(s)
AIDS	HIV-1, HIV-2 ^a
Bacterial vaginosis	<i>Gardnerella vaginalis</i> , <i>Mobiluncus</i> spp., and so on
Chlamydia	<i>Chlamydia trachomatis</i>
Chancroid	<i>Haemophilus ducreyi</i>
Cytomegalovirus disease	Cytomegalovirus
Genital warts	Human papillomavirus
Gonorrhea	<i>Neisseria gonorrhoeae</i>
Donovanosis (granuloma inguinale)	<i>Klebsiella granulomatis</i>
Leukemia, lymphoma	HTLV-I, HTLV-II
Lymphogranuloma venereum	<i>Chlamydia trachomatis</i>
Molluscum contagiosum	Molluscum contagiosum virus
Nongonococcal urethritis	<i>Mycoplasma genitalium</i> , <i>Ureaplasma urealyticum</i>
Pubic lice	<i>Phthirus pubis</i>
Scabies	<i>Sarcoptes scabiei</i>
Syphilis	<i>Treponema pallidum</i> subsp. <i>pallidum</i>
Trichomoniasis	<i>Trichomonas vaginalis</i>

^aHIV-2 is found predominately in sub-Saharan Africa.

AIDS, Acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; HTLV, human T-cell leukemia virus.

sexually transmitted infections (STIs) is more commonly used because it has a broader range of meaning; a person may be infected and may potentially infect others without showing signs of disease.

STIs continue to be a major health threat in the United States and worldwide. According to the World Health Organization (WHO), 376 million new cases of curable STIs (syphilis, gonorrhea, chlamydia, and trichomoniasis) occur throughout the world every year. Additionally, more than 1 million STIs are acquired daily worldwide. In developing countries, STIs and related complications rank in the top five in disease categories for individuals seeking health care. Up to 70% of women and a large percentage of men may show no signs or symptoms of gonococcal or chlamydial infections and therefore do not receive treatment or counseling. Individuals who are unaware of their infection status can thus perpetuate the spread of disease through each new contact.

Without treatment, there are critical implications of STIs for the reproductive, maternal, and newborn health. Because developing countries often have limited resources and testing capabilities, the WHO has developed a syndromic approach to diagnose STIs and treat patients presenting with consistently recognized signs and symptoms of an STI. Although not perfect, this syndromic approach is more accurate than diagnosis based on clinical tests alone. In the United States, the Centers for Disease Control and Prevention (CDC) estimated in 2018 that 26 million new STIs were diagnosed, costing the U.S. health care system \$16 billion in direct medical costs. Current reviews of mandatory reporting data indicate continuing annual increases for syphilis, gonorrhea, and chlamydia. Unfortunately, no trending data are available for STIs that do not require reporting.

The CDC's 2020 surveillance study reports that the increase in 2018 represents a disturbing 185% increase in the congenital syphilis case rate relative to 2014. During this period, a corresponding 165.4% increase in primary and secondary syphilis in women of childbearing age was observed. From 2017 to 2018, newborn deaths from syphilis increased 22%.

The national congenital syphilis rate of 57.3 cases per 100,000 live births in 2020 represents a 15% increase relative to 2019 and a 254% increase relative to 2016. These increases mirror increases in syphilis among reproductive-aged women. During 2019–2020 the rate of primary and secondary syphilis increased 24% among women aged 15 to 44 years. In 2020 there were 5726 cases of syphilis (all stages) diagnosed among pregnant women, an increase of 16% from 2019.

A great disparity of infection rates exists among specific age ranges and among some ethnic and racial groups. Approximately 10,000 teenagers are infected by STIs daily, which averages to about 1 every 8 seconds. About one half of the new infections in the United States occur in persons 15 to 24 years of age, many of whom may develop lifelong health issues. According to the 2020 Sexually Transmitted Diseases Surveillance by the CDC, almost two thirds (61%) of all reported chlamydia cases were among persons aged 15 to 24 years. Gonorrhea and syphilis cases were highest among 20- to 24-year-old men and women.

Disparities also exist among some ethnic and racial groups. The rates of chlamydia, gonorrhea, and syphilis were

5.6 times, 7.7 times, and 4.7 times higher, respectively, among Blacks than among Whites. Much of this may be caused by poorer living conditions, lack of convenient health care resources, or cultural barriers.

Men who have sex with men (MSM) are disproportionately affected. They account for 54% of the syphilis cases, and among these men, 42% have HIV. The incidence of antibiotic-resistant gonorrhea is greater compared with women and men who have sex with women only. The CDC continues to invest resources in prevention efforts to reduce risk behavior and increase STI and HIV testing among populations at greatest risk.

Currently, the CDC recommends annual chlamydia and gonorrhea screening for sexually active women younger than 25 years of age and for older women with risk factors (e.g., new or multiple sexual partners or residing in communities with a high burden of disease). Pregnant women should also be tested for syphilis, HIV, and hepatitis B. Annual screening of MSM for syphilis, gonorrhea, and chlamydia is recommended. HIV screening is recommended at least once for everyone between 13 and 64 years of age and annually for anyone not practicing safe sex or sharing injection drug supplies. Although these screening and prevention programs have been proven cost-effective and beneficial to the public, more has to be done to stem the tide because approximately 50% of those who should be screened are actually tested. Unfortunately, many people still engage in risky sexual behavior, even after receiving a diagnosis of an STI, which can be correlated with increased drug use.

In 2018, four of the top 10 reportable diseases in the United States were STIs (chlamydia, gonorrhea, syphilis, and HIV infection; [Table 38.2](#)). STIs have diverse causative agents, signs and symptoms, prognoses, and methods for laboratory testing. This chapter will discuss common symptoms of STIs and review exudative infections (gonorrhea, chlamydia, vulvovaginitis), ulcerative infections (syphilis, chancroid, genital herpes), HIV infection, and other STIs.

Table 38.2 Top 10 reportable diseases in 2018

Disease, organism	Cases reported (/100,000)
Chlamydia	537.54
Gonorrhea	178.32
Syphilis—total, all stages	35.16
Campylobacteriosis	21.46
Salmonellosis	18.64
Coccidioidomycosis	11.58
Lyme borreliosis	10.34
Human immunodeficiency virus	10.09
<i>Streptococcus pneumoniae</i> , invasive disease	8.14
Giardiasis	6.06

Urethritis

Causes

Urethritis is the most common STI syndrome recognized in men and is often seen in women with coinciding cervicitis. **Urethritis** is an inflammation of the urethra, which can be caused by mechanical injury (catheterization), chemical irritation (antiseptics), or infectious disease. Infectious urethritis is usually associated with organisms that cause STIs, such as *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, which clinically manifest as exudates. Cases can be divided into two types based on causation: gonococcal urethritis and **nongonococcal urethritis (NGU)**. In males, gonococcal urethritis can be presumptively diagnosed with direct Gram-stained smears of urethral exudates, which will demonstrate WBCs with gram-negative intracellular diplococci suggestive of *N. gonorrhoeae*. Because women have normal biota resembling *N. gonorrhoeae*, a similar finding in endocervical exudates must be supported by either culture or a nonculture assay.

NGU, which can have infectious and noninfectious causes, is diagnosed similarly when inflammation (WBCs) is detected with no organisms seen on direct Gram-stained smears. Most NGU cases cannot be attributed to any specific agent. Infection with *C. trachomatis* is the most common cause of NGU (15% to 55% of cases) and is the most commonly reported infectious disease in the United States. Less frequent causes of NGU include *Ureaplasma urealyticum*, *Mycoplasma genitalium*, *Trichomonas vaginalis*, herpes simplex virus (HSV), and adenovirus. Gonococcal urethritis and NGU infections are not mutually exclusive. Many patients are often co-infected with *N. gonorrhoeae* and *C. trachomatis*, with rates as high as 20% in men and 42% in women.

Case check 38.1

The two main causative agents of urethritis are *N. gonorrhoeae* and *C. trachomatis*. In males presenting with a purulent exudate or discharge, direct Gram-stained smear of the discharge demonstrates many polymorphonuclear cells with intracellular gram-negative diplococci, which are a strong predictor of gonococcal infection. Generally, WBCs noted in a urethral exudate are suggestive of an infection. In the Case in Point, the patient had a discharge that demonstrated WBCs but no organisms. Clearly, he had urethritis, but without further testing it is impossible to determine the causative agent. Some patients can have a co-infection with *N. gonorrhoeae* and *C. trachomatis*. In general, most patients presenting with symptoms of urethritis are treated with antimicrobials effective against both organisms. The patient's girlfriend was also given antimicrobials despite not having any symptoms.

Epidemiology

Gonorrhea is the second most commonly reported infectious disease in the United States. According to the CDC, 677,769 cases of gonorrhea were reported in 2020 in the

United States. The overall rate of reported gonorrhea increased 5.7% during 2019–2020. However, the CDC estimates that only 50% of new infections are reported, indicating a high probability that over 1,000,000 people contract new gonorrheal infections each year. Rates of reported gonorrhea have increased 111% since the historic low in 2009, although there was a slight decrease in 2013, followed by a yearly increase during 2013–2020 (Fig. 38.1). Rates have been higher among men compared to women since 2013 when cases were identified in both men who have sex with men (MSM) and men who have sex with women only. However, during 2019–2020, the CDC reported that rates among women were greater (15%) than among men (6.6%), suggesting the differences in diagnosing and reporting of cases among MSM in 2020.

The highest incidence of gonorrhea continues to be found among sexually active adolescents and young adults from 15 to 24 years of age. Worldwide, gonorrhea rates have also continued to increase over the past 20 years, with an estimated 86.9 million new cases reported annually. Many of these infected individuals are asymptomatic (approximately 80% of women, 10% of men), which is a cause of concern with regard to treatment and control, especially because individuals with one known STI typically have a lifestyle that puts them at higher risk of becoming infected with HIV or other agents.

Chlamydia is the most commonly reported infectious disease in the United States and is caused by the obligate intracellular parasite *C. trachomatis*. There are 19 serovars in total. Serovars A, B, Ba, and C are isolated from trachoma, an eye infection that leads to blindness and is endemic in developing countries, mainly Africa. Serovars D to K are those associated with the genital tract disease chlamydia. Serovars L1, L2, L2a, L2b, and L3 are associated with **lymphogranuloma venereum (LGV)** (discussed later).

Rates of reported chlamydial infections have substantially increased since the mid-1990s. Public programs for screening and treatment of women were established to avert **pelvic inflammatory disease (PID)** and related complications. Several clinical trials evaluating the effectiveness of screening for the prevention of PID demonstrate that it is an effective intervention to reduce risk in young women. However, expansion of screening tests remains a priority. Chlamydia rates for women in 2018 were nearly two times higher than for men (692.7 vs. 380.6 per 100,000 persons). Worldwide, the rates of reported cases of chlamydia continue to increase, currently with about 127.2 million new cases reported annually.

In 2020, the CDC reported a total of 1,579,885 cases of genital *C. trachomatis* infection (Fig. 38.2). The national rate of reported chlamydia, 481.3 cases per 100,000 population, decreased by 13% compared with the rate in 2019. Although the rates of reported chlamydia decreased among both males and females in 2019–2020, the CDC supposed that the decreases were not probably due to decrease in new infections. Rather, during the COVID-19 pandemic, many health care clinics limited in-person visits to patients with symptoms or closed entirely. Because chlamydial infections are usually asymptomatic and are usually detected during annual reproductive health visits when STD screening are performed, such visits decreased in 2019–2020.

Fig. 38.2 Chlamydia: rates of reported cases by sex, United States, 2011–2020. (From Centers for Disease Control and Prevention. (2020). *Sexually transmitted disease surveillance 2020*. Atlanta: Centers for Disease Control and Prevention.)

Clinical manifestations

Gonococcal urethritis causes an acute infection with dysuria and urethral discharge usually without urinary frequency or urgency. *N. gonorrhoeae* binds specifically to columnar epithelial cells of the genitourinary tract, including the urethra, cervix, endocervix, and Bartholin glands. The organism also attaches to columnar epithelial cells of the anal canal, pharynx, and conjunctiva. From the time of exposure to the onset of symptoms, the incubation period averages 2 to 7 days, after which 90% or more of men experience a purulent urethral discharge, with the remaining 10% being asymptomatic (Fig. 38.3A). Infected women often have no symptoms for weeks or months, and the disease may be discovered only after being examined as a sexual contact of a male partner who tested positive for the disease.

The incubation period of NGU is 7 to 21 days, with symptoms arising less abruptly. Symptoms of urethritis in women include dysuria or pyuria and, less often, urethral discharge. Because urethritis in women is often accompanied by cervicitis (70% to 90%), a woman may also experience abnormal cervicovaginal discharge, intermenstrual bleeding, and pain

during or after vaginal sex. Patients with NGU are much more likely to be asymptomatic compared with patients with gonococcal urethritis. In symptomatic patients, NGU often results in a urethral discharge that is less profuse and more mucoid compared with that from gonococcal urethritis (see Fig. 38.3B). Dysuria without urethral discharge may be present in these patients.

If left untreated, spontaneous resolution occurs in most cases of urethritis in men; however, complications of ascending infection include acute prostatitis, **epididymitis** (a painful inflammation of the coiled tube [epididymis] at the back of the testicle), and urethral stricture. Ascending infection occurs in 10% to 20% of women with undiagnosed infections. These women are in danger of developing PID presenting as **salpingitis** (inflammation of the fallopian tubes), endometritis, internal abscesses, and chronic pelvic pain. Women with PID do not always have symptoms, but when symptoms are present, they can be very severe and can include lower abdominal pain, abnormal cervical discharge and bleeding, and fever. According to the American College of Gynecology, each year about 1,000,000 women in the United States develop acute PID, and more than 100,000

Fig. 38.3 **A**, Purulent urethral discharge in a patient with gonorrhea. **B**, Case of nonspecific urethritis with accompanying mild meatitis and mucoid urethral discharge. (A, From Marx. J., et al. [2010]. *Rosen's emergency medicine: concepts and clinical practice* (7th ed.). Philadelphia: Mosby; B, Courtesy Jim Pledger, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

Fig. 38.4 **A**, Gram stain of a urethral exudate sample from a male with suspected urethritis ($\times 1000$). Numerous polymorphonuclear leukocytes are visible, confirming urethritis; however, no organisms are evident. This specimen proved to be negative for the presence of *Neisseria gonorrhoeae*. **B**, Gram stain of an acute case of gonococcal urethritis demonstrating gram-negative intracellular diplococci within leukocytes (arrows) ($\times 1000$). (A, Courtesy Dr. Norman Jacobs, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA; B, Courtesy Joe Miller, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

of them will become infertile. In 0.5% to 3% of untreated cases of gonococcal urethritis, *N. gonorrhoeae* will invade the bloodstream and result in disseminated gonococcal infection. Perinatal exposure to *N. gonorrhoeae* and *C. trachomatis* can result in severe disease in newborns, including sepsis, pneumonia, inclusion conjunctivitis, and ophthalmia neonatorum, which can result in perforation of the globe of the eye and blindness.

Laboratory diagnosis

Urethritis can be diagnosed on the basis of the presence of mucopurulent or purulent urethral discharge; demonstration of two or more leukocytes per high-power field in a smear of urethral exudate; and a positive leukocyte esterase test result on first-morning voided urine or microscopic examination

of more than 10 WBCs per high-power field of first-morning voided urine sediment (Fig. 38.4A). Because of the potential for co-infection, the CDC recommends that all patients with confirmed or suspected urethritis be tested for gonorrhea, chlamydia, and HIV infection. Gram stain of male urethral exudate that demonstrates WBCs with gram-negative intracellular diplococci is considered a presumptive diagnosis (>99% specific and >95% sensitive) for *N. gonorrhoeae* in symptomatic men (see Fig. 38.4B). The sample is usually obtained by passing a small swab a few centimeters into the urethra or by milking any exudate onto a slide for staining. Because of the lower sensitivity, a negative Gram-stained smear result should not rule out gonococcal infection in asymptomatic males. If none of these criteria are present, the patient should be tested for *N. gonorrhoeae* and *C. trachomatis* and followed closely if test results are negative.

N. gonorrhoeae and *C. trachomatis* can be isolated in culture. *N. gonorrhoeae* is a fastidious organism that requires a selective growth medium (modified Thayer-Martin, Martin-Lewis, New York City media) in a carbon-dioxide (CO₂)-rich environment for culture. Cell culture using McCoy cells is considered the gold standard for chlamydia diagnosis. However, the testing method recommended for the most common organisms associated with urethritis is nucleic acid amplification tests (NAATs). NAATs are recommended for detection of *N. gonorrhoeae* and *C. trachomatis* because of their high sensitivity and specificity and the ease of specimen transport. There are several U.S. Food and Drug Administration (FDA)-approved NAATs available (Table 38.3).

Initially, approved specimens for testing via molecular assays included a first-morning voided urine sample or swabs from vaginal, endocervical, and urethral exudates. In May 2019, the FDA approved the Aptima Combo 2 Assay (Hologic, Marlborough, MA) and the Xpert CT/NG (Cepheid, Sunnyvale, CA) for extragenital diagnostic testing for gonorrhea and chlamydia using throat and rectal samples. The continued development of improved assays with increased testing percentages will hopefully result in earlier diagnosis and treatment for these patients.

Treatment

Treatment of patients presenting with urethritis should be initiated immediately to eradicate the organism. Originally, penicillin was the agent of choice for treating gonorrhea; however, penicillinase-producing *N. gonorrhoeae* strains developed. Fluoroquinolone agents, such as ciprofloxacin, replaced penicillin in the mid-1990s because of their greater efficacy, availability, and use as a single-dose, oral therapy. However, fluoroquinolone resistance began to increase rapidly by the early 2000s, becoming widespread in the United States and necessitating another change in treatment regimens. The

CDC currently recommends intramuscularly administered ceftriaxone for uncomplicated gonococcal infections.

Because many patients with gonorrhea may also be co-infected with *C. trachomatis*, the CDC recommends treatment with an antimicrobial regimen effective against both pathogens, such as ceftriaxone plus a single dose of azithromycin or doxycycline for 7 days. Alternative regimens include erythromycin, levofloxacin, or ofloxacin.

Recent reports indicate development of resistance against azithromycin and extended-spectrum cephalosporins. This is a cause of great concern because most therapeutic options for treatment may no longer be useful. In addition, with most cases of gonorrhea identified through molecular methods, there is no available culture to perform susceptibility testing. With few actual specimens submitted for culture, it becomes difficult to estimate accurately the antimicrobial resistance burden until after initial therapy fails in a patient. This portends a need to collect more specimens for culture and susceptibility testing and/or to identify and develop molecular tests for known antimicrobial resistance markers. In the meantime, patients should return for follow-up evaluation if symptoms continue despite therapy or recur after its completion. Sexual partners of these patients should be notified and treated. To avoid reinfection, partners are encouraged to abstain from sexual intercourse until therapy is completed.

Cervicitis

Causes

Cervicitis, an inflammation of the columnar and subepithelial cells of the endocervix, can be caused by infectious and noninfectious means. The infectious cases are more common and almost always associated with *C. trachomatis* and/or

Table 38.3 Molecular tests for gonorrhea and chlamydia approved by the U.S Food and Drug Administration

N. gonorrhoeae. Cervicitis can also result from trichomoniasis, genital herpes, or infections by *Mycoplasma* and *Ureaplasma*. Noninfectious inflammation occurs from injury to the cervix, usually as a result of a foreign object being inserted into the vagina, such as a birth control device, douche, or tampon. Chemical irritation can also occur because of the use of these products.

Epidemiology

Cervicitis is a very common condition, with more than 50% of all women developing it at some time in their adult lives. It is the most common STI in adolescent girls. Common risk factors for development of disease include beginning sexual activity at an early age, engaging in high-risk sexual behaviors, history of STIs, and having multiple sexual partners. It is considered the “silent partner” of male urethritis because symptoms are not always obvious, so many women may not feel the need to seek health care from a licensed provider. The lack of well-recognized symptoms and signs of cervicitis makes diagnosis very difficult. Patients in whom symptoms are not noted or recognized do not receive any treatment, and this leads to serious complications, such as PID, infertility, ectopic pregnancy, chronic pelvic pain, spontaneous abortion, and even cervical cancer.

Clinical manifestations

Symptoms of cervicitis, if present, may be fairly mild initially and progress over time. The most common symptom is a vaginal discharge that may be grayish or yellow, possibly with an odor. Other signs include abnormal bleeding, itching, irritation of the external genitalia, pain during intercourse, bleeding or spotting after intercourse, dysuria, and sometimes lower back or abdominal pain. Severe cases may demonstrate a profuse, almost puslike discharge accompanied by vaginal itchiness or abdominal pain.

Case check 38.2

Cervicitis is often difficult to diagnose because many of the symptoms may be mild or unrecognized. In some cases, symptoms may not be evident until much later, when potential complications, such as PID, chronic pelvic pain, ectopic pregnancy, or infertility, occur. By tracing all sexual contacts of an individual suspected of having an STI, it is hoped that screening and treatment can be performed before devastating sequelae occur. In the Case in Point, the patient's girlfriend did not complain of genital pain or dysuria, but she was also given antimicrobials in case she had an asymptomatic infection at the time.

Laboratory diagnosis

The diagnosis of cervicitis is generally performed clinically. However, microscopic analysis showing more than 10 WBCs per high-power field of exudate has been associated with chlamydial and gonococcal infection of the cervix. Whereas gram-negative intracellular diplococci from

urethral exudates are presumptive diagnostic of gonococcal infection in men, direct Gram-stained smear of cervical exudates is at most 50% accurate and is not commonly used. Most women presenting with symptoms of cervicitis are assessed for signs of PID and tested for *C. trachomatis* and *N. gonorrhoeae*. However, because the female genital tract is contiguous, there is some overlap between vulvovaginitis and cervicitis. Thus, if warranted, patients should also be evaluated for **bacterial vaginosis (BV)** and trichomoniasis.

Culture for any of these organisms lacks sensitivity compared with nucleic acid–based assays. The most common are the amplified tests, with very high rates of sensitivity and specificity (>95%). There are several FDA-approved assays available in automated and nonautomated formats (see Table 38.3). Rapid antigen tests are also available for point-of-care (POC) testing or physicians' office laboratories for chlamydia, *Neisseria*, trichomonads, and BV, but not for the Mycoplasmataceae. Although useful in the health care provider's office setting, the lack of sensitivity may require additional testing for confirmation of infection.

Treatment

Treatment options differ according to the organisms suspected or detected. Empiric therapy should be provided to patients with high-risk factors (age ≤ 25 years, new or multiple sexual partners, and unprotected sex), especially if there is a possibility that they will be lost to follow-up. As discussed previously, patients with *N. gonorrhoeae* and/or *C. trachomatis* are usually treated with multiple agents, including a cephalosporin and doxycycline or a macrolide, such as azithromycin or erythromycin, thus providing coverage for both organisms and lessening the chances of garnering resistance. Cases of trichomoniasis or BV are usually treated with metronidazole.

Women with persistent cervicitis should be evaluated for possible re-exposure to an STI or perhaps switched to a different antimicrobial regimen. Follow-up is recommended to ensure eradication of the organism(s). Sexual partners should also be notified and treated. The patient and partner(s) are encouraged to abstain from sexual intercourse to avoid reinfection until therapy is completed.

Vulvovaginitis

Causes

Vaginal infections account for more than 10 million visits to a health care provider annually. Vaginitis occurs when the mucosal lining of the vagina becomes inflamed and irritated. Bacteria, yeasts, or viruses are the main infectious causes, but chemical or mechanical irritants, such as feminine hygiene products, soaps, contraceptives, and some clothing, can also cause vaginitis. Typical signs include vaginal discharge, vulvar itching and irritation, and often odor. Three commonly associated diseases with these symptoms are BV, trichomoniasis, and candidiasis. The distinction among these diseases can initially be made by observations of the vaginal discharge.

Bacterial vaginosis

Epidemiology

BV is the most common vaginal infection in women of child-bearing age, although the role of sexual activity in women developing BV is still unclear. Prevalence in the United States is currently estimated to be 21.2 million (29.2%) among women 14 to 49 years of age based on a National Health and Nutrition Examination Survey (NHANES) report. Additional study findings noted that most women with BV (84%) were asymptomatic, and even though most sexually naïve women were rarely affected, they could also develop the infection. Most cases occur in sexually active women, with an increase in prevalence rates depending on the overall number of sexual partners. Risk factors for developing BV are dependent on a number of socio-demographic characteristics, such as initiating sexual activity at an early age; having numerous, anonymous, or frequently changed sexual partners; having female sexual partners; ethnicity (African Americans and Mexican Americans are at higher risk); and even frequent douching, which is thought to eliminate much of the normal protective lactobacilli.

Clinical manifestations

BV occurs when the delicate balance of the normal vaginal microbiota is disrupted and replaced by an overgrowth of specific organisms. In healthy women, the vaginal biota comprises mainly *Lactobacillus* spp., which maintain a pH between 3.8 and 4.5 to prevent the overgrowth and invasion of pathogenic bacteria by competitive exclusion, competition for nutrients, and release of antimicrobial substances, such as hydrogen peroxide, organic acids, bacteriocins, and biosurfactants. Thus, when vaginal lactobacilli are depleted, vaginal pH increases, allowing the overgrowth of various bacterial species, including *Gardnerella vaginalis*, *Mycoplasma hominis*, *Ureaplasma* spp., and anaerobes, such as *Prevotella*, *Porphyromonas*, *Peptostreptococcus*, and *Mobiluncus*. This mix of organisms leads to the development of an abnormal vaginal discharge, with a distinct unpleasant odor similar to that of rotting fish but lacks a true inflammatory reaction. Patients with BV demonstrate a discharge that is usually a milky, homogeneous, thin liquid adhering to the walls of the vagina. Discharge is often more apparent and odorous after intercourse (exposure to male ejaculate).

Laboratory diagnosis

BV can be diagnosed by using clinical criteria (i.e., Amsel diagnostic criteria) or Gram stain (considered the gold standard) of the vaginal discharge. The Amsel diagnostic criteria for BV require that three of the following four criteria be met: (1) clue cells on microscopic examination; (2) a thin, white, and homogeneous vaginal discharge; (3) a vaginal pH greater than 4.5; and (4) a fishy odor when 10% potassium hydroxide (KOH) solution is added to vaginal secretions ("whiff test"). Microscopic examination of the discharge is performed to look for the presence of clue cells, vaginal squamous epithelial cells typically coated with gram-variable *G. vaginalis*. Clue cells are identified with microscopic examination of a vaginal saline wet mount preparation or Gram stain. Normal vaginal squamous epithelial cells have distinct cell margins

and lack granularity, whereas clue cells tend to show sheets of coccobacillary organisms attached in clusters on the cell surface, making the border indistinct or stippled (Fig. 38.5). Polymorphonuclear leukocytes can also be demonstrated on the normal vaginal wet mount preparation but are rarely noted in cases of BV in the midst of clue cells.

Because of the lack of lactic acid-producing organisms to maintain an acidic environment, the vaginal pH begins to increase. This can be measured by using pH test paper to test the vaginal discharge and determine whether the vaginal environment is within the reference range. The amine or whiff test can also determine if the vaginal pH is higher than 4.5. This is performed by adding 1 or 2 drops of 10% KOH to the vaginal discharge and subsequently detecting a fishy odor. The odor is caused by volatilization of amines as a by-product of anaerobic metabolism. An alternative to the Amsel criteria is the use of direct Gram stain of vaginal secretions. Stained smears are read, and the numbers of morphotypes (*Lactobacillus*, *Gardnerella*, and *Mobiluncus*) present are scored using the Nugent scoring system (see Chapter 16).

Laboratory testing can also be performed to confirm BV by submitting a vaginal discharge specimen for culture. Identification of *G. vaginalis* is possible but usually presumptive, requires the use of specialized media, and is discouraged because of lack of specificity. The deoxyribonucleic acid (DNA) hybridization test Affirm VPIII (BD Diagnostic Systems, Sparks, MD) detects the most common causes of BV and vaginitis: *G. vaginalis*, *Candida* spp., and *T. vaginalis*. This test is easy to perform and can be completed in less than 1 hour but requires technical expertise and additional equipment. It definitively identifies the causative organism, thus providing focused therapy for the patient. Rapid card tests for use in a physician's office laboratory can detect proline aminopeptidase activity indicative of *G. vaginalis* in vaginal fluid specimens. Another POC option is the OSOM BV Blue test (Sekisui Diagnostics, Burlington, MA). It detects vaginal fluid sialidase, an enzyme associated with *G. vaginalis*, *Bacteroides*, *Prevotella*, and *Mobiluncus* with performance characteristics comparable to Gram stain.

Fig. 38.5 Microscopic saline preparation of vaginal squamous epithelial cells with numerous bacteria (*Gardnerella vaginalis* attached; $\times 400$). Combined, these are identified as clue cells and are key indicators of bacterial vaginosis. (Courtesy M. Rein, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

Treatment

BV is usually treated with an oral or a topical antimicrobial agent, such as metronidazole or clindamycin. Oral metronidazole therapy 500mg is a twice-daily, 7-day course, whereas metronidazole gel (0.75% one full applicator [5g]) or clindamycin cream (2% one full applicator [5g]) is applied intravaginally once a day for 5 and 7 days, respectively. The bacterial infection usually resolves within a few days, but a longer therapeutic period may become necessary if it recurs. Treatment is provided to relieve symptoms and reduce the risk of infectious complications with other organisms. BV in pregnancy can lead to potential adverse outcomes, such as preterm labor, low birth weight, premature rupture of membranes, and miscarriage. Thus pregnant women at high risk (previous preterm birth) should be managed carefully.

Case study

A 24-year-old female patient notes vaginal itching and irritation with a slight discharge. Previously, she had a yeast infection that had been successfully treated with over-the-counter (OTC) medications. Thinking that this was a recurrence, she self-treated again. This time, however, the symptoms did not resolve, and now there is a frothy discharge with a pungent odor. She presents to her health care provider for diagnosis, and the nurse practitioner takes a swab of the secretion to perform a rapid POC test and microscopy. A wet mount of the specimen demonstrates motile organisms.

Trichomoniasis

Epidemiology

Trichomoniasis, caused by the parasitic protozoan *Trichomonas vaginalis*, is the most common STI worldwide, according to the WHO, with approximately 156 million new cases among men and women 15 to 49 years of age reported each year. The greatest concentration of infections occurs in Southeast Asia and sub-Saharan Africa. It is a very common infection in the United States. The CDC estimates that 3.7 million people in the United States are infected with *T. vaginalis*, approximately 70% of whom show no signs or symptoms of infection. Although infections occur mostly in women, their male partners may also become infected. *T. vaginalis* infections are commonly associated with other STIs, in particular BV or gonorrhea. The number of cases of trichomoniasis is evenly distributed across all age groups and may be considered a useful marker for risky sexual behavior. Because this infection is easily cured and is not a reportable disease, it receives little emphasis from public health STI control programs and has a much lower priority compared with chlamydial and gonorrheal infections.

Clinical manifestations

Trichomoniasis demonstrates generalized symptoms of differing severity, ranging from mild irritation to severe

inflammation. Women typically report itching, burning, dysuria, lower abdominal pain, genital redness or soreness, and an odorous vaginal discharge that can be clear, white, yellowish, or greenish (Fig. 38.6). The vaginal discharge also has an elevated pH, between 5.0 and 6.0. The cervix demonstrates a punctate and papilliform appearance, which gives the appearance of a strawberry, hence the term *strawberry cervix* (Fig. 38.7). This feature is best detected by colposcopy and rarely during routine examination.

The high rate of asymptomatic infections makes screening very important in reducing overall infection. The severity of symptoms depends on a multitude of factors that influence

Fig. 38.6 Yellowish-green frothy purulent discharge from the cervical os, demonstrative of trichomoniasis. (Courtesy Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

Fig. 38.7 Presentation of a strawberry cervix caused by a *Trichomonas vaginalis* infection. The cervical mucosa reveals punctate hemorrhages along with accompanying vesicles or papules. (Courtesy Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

the host inflammatory response, such as hormonal levels, coexisting vaginal biota, and the strain and relative concentration of the organisms present in the vagina. Additionally, some of the virulence factors of this organism are adherence factors, which enable colonization of cervicovaginal epithelial cells, and cysteine proteases, which degrade host extracellular matrix proteins.

Male sexual partners can also be infected with *T. vaginalis*, presenting with symptoms of NGU. A number of complications are associated with infection by *T. vaginalis*. Cellulitis has been seen in some patients following hysterectomy. A significant correlation has been found between infection and low birth weight, premature rupture of membranes, and preterm delivery. African studies also confirm increased potential for acquisition of HIV infection with *T. vaginalis* infection.

Laboratory diagnosis

Trichomoniasis can be easily determined through visualization of motile trichomonads in a saline preparation of vaginal fluid (Fig. 38.8). Physicians may perform this test in the clinic because organisms lose viability quickly after collection of the sample. This is allowable under Clinical Laboratory Improvement Amendments (CLIA) rules as provider-performed microscopy. Despite the ease of the test, it has limited sensitivity, ranging from 60% to 70%. Culture is still considered the gold standard, which requires Diamond medium, although this is not widely available. A commercially available IPouch TV self-contained culture media device (Biomed Diagnostics, White City, OR) has been demonstrated to be as good as culture and has been used successfully with clinician-obtained and self-obtained specimens. A delayed inoculation technique is also possible, allowing initial reading of the wet mount preparation and then inoculation of the culture pouch if the wet mount preparation is negative. Swab specimens may sit at room temperature for up to 30 minutes before pouch inoculation.

Newer commercially available methods for diagnosis include an office-based oligonucleotide probe test (Affirm VPIII, BD Diagnostic Systems) and a POC rapid antigen detection test (OSOM *Trichomonas* rapid test, Sekisui Diagnostics). The approximate sensitivity of these assays ranges from 71.4% to 83 compared with wet mount. These tests may be of

Fig. 38.8 Phase contrast wet mount micrograph of vaginal discharge revealing the presence of *Trichomonas vaginalis* protozoa surrounding a squamous epithelial cell ($\times 200$). (Courtesy Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

value in settings in which microscopy is not possible. Several high-throughput nucleic acid amplification platforms have been FDA approved. These include the BD Probe Tec TC Q^x Amplified DNA assay (BD Diagnostic Systems), Aptima TV assay (Hologic), Xpert TV assay (Cepheid), and AmpliVue *Trichomonas* assay (Quidel, San Diego CA).

Treatment

Metronidazole is the drug of choice for treating trichomoniasis. Approximately 4% to 10% of all cases display some level of resistance to treatment with metronidazole, although this can usually be overcome with higher oral doses. Patients who are allergic to metronidazole may be treated with tinidazole, which actually has a longer half-life for a shorter therapeutic duration. All sexual partners should be treated, along with patients with asymptomatic infection. Otherwise, if left untreated, they may later become symptomatic, and transmission of infection will continue.

Candidiasis

Epidemiology

Vulvovaginal candidiasis is symptomatic vaginitis caused by infection with the yeast *Candida*. Almost all cases of infection are caused by *C. albicans*, with only a small percentage caused by other species of *Candida* (*C. glabrata*, *C. parapsilosis*, *C. tropicalis*, *C. krusei*). Yeast infections are also termed *vaginal thrush* or *moniliasis*. Infection is very common, with almost 75% of all adult women having had at least one genital yeast infection in their lifetime. *Candida* is always present in the body in small amounts, so when an imbalance occurs, such as changes in the acidity of the vagina, symptoms manifest. Vaginal candidiasis is not considered a true STI, but it is included in this discussion because it causes symptoms in the female genital tract that are similar to the organisms described earlier. Rarely, candidal infections can be passed sexually to male partners, but these infections are usually not serious and respond well to treatment.

Yeast infections are the most common genital infections affecting women. Infections occur as a result of changes in the vaginal biota. In many cases, infection may follow a course of broad-spectrum antimicrobials that were administered for another purpose but inadvertently eliminated the normal biota. Hormonal causes of yeast infections include pregnancy, ovulation, menopause, oral contraceptives, and estrogen replacement therapy. Immunosuppressive conditions, such as diabetes mellitus, iron deficiency, or HIV infection, will also lead to an increased infection rate. Finally, various skin conditions (psoriasis, lichen planus, or lichen sclerosus) can lead to infection. The highest prevalence of infections occurs typically in women of childbearing age who are producing ample amounts of estrogen, which causes the lining of the vagina to mature and contain glycogen, a preferred growth substrate for *C. albicans*.

Clinical manifestations

Women with vulvovaginal candidiasis usually experience vulvar itching, burning, pain, swelling, or redness with an abnormal vaginal discharge ranging from a slightly watery, white discharge to a thick, white, cottage cheese

Fig. 38.9 Candidal cervicitis caused by *Candida* spp. The cervical discharge is white, thick, and curdlike. (Courtesy Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

curd-like discharge (Fig. 38.9). Additional signs and symptoms include vulvar inflammation and redness, sometimes spreading widely in the groin to include the pubic area, inguinal area, and thighs; pain during intercourse; and painful urination. Males who develop genital candidiasis demonstrate an itchy rash or burning at the foreskin or head of the penis called **balanitis**.

Laboratory diagnosis

The diagnosis of yeast infections is typically done clinically. Discharge can be submitted for microscopy and culture to rule out other causative agents of vaginosis. Microscopic evaluation of a yeast infection demonstrates budding yeast forms on Gram-stained smears and KOH preparation. The pH of the vaginal fluid remains unchanged as opposed to an elevated pH with BV and trichomoniasis.

Treatment

Yeast infections are typically treated with OTC medications or prescription antifungal agents. In most cases, symptoms usually disappear completely with adequate treatment. However, recurrences are possible that may signal some other underlying health issues, such as immunosuppression. Numerous antifungal drugs, both prescription and OTC medications, are available to treat yeast infections, but all are essentially azole antifungal agents that inhibit the production of ergosterol, which is an important component of the fungal plasma membrane. Such agents are available as suppositories, topical creams or lotions, and oral pills. The agent used may depend on whether the infection is self-diagnosed or diagnosed by a health care provider. The duration of therapy is agent specific and can correspond to as little as a single dose or treatment lasting up to 7 days. Women with first-time infections should seek advice from their provider as should those who seem to have a chronic or recurrent form of disease (four or more proven episodes). Women with a weakened immune system may require a longer therapeutic regimen and should also consult their provider before resorting to self-treatment.

Despite therapy, chronic or recurrent infections may still occur. This may be from inadequate initial treatment, or perhaps a secondary infection may develop as a result of prolonged scratching, causing the skin of the vulva to become cracked and raw. In many cases, women will opt to self-treat as opposed to visiting their health care provider to save time and money. However, unless women are fully aware of the signs and symptoms of candidiasis, their diagnosis may be incorrect. A high percentage of all OTC drugs sold to treat candidiasis were probably used by women without the disease, thus increasing the drug resistance rate. It is now thought that women who experience recurrent yeast infections have persistent infection and not reinfection.

Methods of prevention suggested to reduce the incidence rate of yeast infections include taking antimicrobials as prescribed and managing diabetes by keeping blood glucose levels under control. Other methods include wearing cotton undergarments and loose-fitting clothing to avoid persistent and excessive moisture in the genital area. Women should avoid wearing wet bathing suits or exercise clothing for long periods. Douching can kill bacteria that help control the growth of *Candida* and is therefore not recommended. Prescription oral medications may be taken regularly on the recommendation of the health care provider. Treatment of the sexual partner is not recommended unless balanitis is present.

Case check 38.3

Vulvovaginitis is one of the most common reasons why females seek medical attention or treatment. In many women, all three causes of disease (i.e., non-lactic acid-producing bacteria, *Candida* spp., or *Trichomonas*) can initially produce asymptomatic infections. In the Case in Point, the girlfriend is at a higher risk of developing one or more of these forms throughout her lifetime because of her young age, especially if she has had multiple sexual partners and participates in unprotected sex (no barrier, e.g., condom).

Genital ulcer disease

Causes

Genital ulcer disease is characterized by a disruption of the skin and/or mucosal layer of the genital region. In the United States, most patients who present with genital ulcers have herpes, syphilis, or chancroid. Less common causes of genital ulcers include LGV and donovanosis. The frequency of each infection differs by geographic area and patient population; however, genital herpes is the most prevalent of these diseases. Multiple infections may be present in a patient with genital ulcers. Agent-specific diagnosis based solely on clinical evaluation of the ulcers is often confounded by the overlapping patterns of clinical presentation and occurrence of multiple and mixed infections. It is very important to successfully treat genital ulcer disease because studies have demonstrated higher susceptibility to multiple STIs, especially an increased risk of HIV susceptibility and transmission.

Case study

A 14-day-old female infant is brought to her pediatrician with a 2-week history of eye discharge. The infant was delivered vaginally at full term. Following delivery, the infant continued to squint, only opening her eyes in the dark. She was referred to an ophthalmologist, who noted large, bilateral corneal ulcers. These ulcers were scraped and submitted for culture, which grew HSV type 2. When the patient's mother was questioned about any illnesses during pregnancy, she mentioned a scabby labial rash and dyspareunia (abnormal pain during sexual intercourse caused by a spasm) during the pregnancy, which resolved after about 1 week. Serologic testing of the mother was also positive for HSV.

Genital herpes

Epidemiology

Genital herpes is a chronic viral infection caused by HSV. There are two serotypes of HSV, HSV-1 and HSV-2, both of which can cause genital herpes, but HSV-2 is more commonly detected (about 90% of the time). Although HSV-2 typically affects the genital area via sexual contact, HSV-1 is mainly associated with an oral infection of the lips, gums, tongue, and other areas inside the mouth, commonly referred to as *cold sores* or *fever blisters*, occurring primarily through orofacial contact. Both serotypes produce mucosal ulcers that are clinically indistinguishable.

Reports from a variety of clinical settings reveal that genital herpes is the most common patient request for treatment of symptomatic genital ulcers in the United States. According to the NHANES and the National Disease and Therapeutic Index (NDTI), the prevalence of HSV-2 infection increased dramatically from 1976 to 1991 and again from 2002 to 2009. There was a slight increase during 2011 to 2012, however recent studies suggest that the upward trend of HSV-2 seroprevalence has been reversed. HSV infections are not nationally reportable diseases, so determination of new infections is based on initial office visits in office practices reporting to the NDTI. The CDC estimated the prevalence of HSV-2 in 2018 at over 18 million, with approximately 1.3 million infections in the 15- to 24-year age group. Genital HSV-2 infection is more common in women than in men (15.9% vs. 8.2%). This disparity is most likely because male-to-female transmission is more prevalent than female-to-male transmission. From 70% to 90% of infected individuals are unaware of their infections because they are asymptomatic or have only vague symptoms. Many patients with subclinical disease have episodes of viral shedding from anogenital sites and represent a significant reservoir of transmission.

Clinical manifestations

HSV infection of oral or genital tissue is initiated by mucosal contact with an active (primary or recurrent) infection of another individual. The virus enters the body through direct sexual contact of skin or mucous membranes with the secretions or mucosal surfaces of an infected person. Incubation periods range from 2 to 14 days after initial exposure. Most individuals with genital herpes are asymptomatic or show minimal signs or symptoms and have not received a

diagnosis of genital herpes. Despite a lack of symptoms, these patients continue to shed HSV into the genital tract intermittently. Therefore the disease is often transmitted by those who are unaware that they are infected or who are asymptomatic when transmission occurs.

In symptomatic patients, primary infection with HSV-2 manifests with extensive, painful vesicles, fever, myalgia, malaise, dysuria, and inguinal lymphadenopathy. These systemic effects are usually limited to the primary episode. About 10% of primary genital HSV-2 infections also result in herpes meningitis, which usually resolves without complications within 1 week. Primary lesions last 2 to 6 weeks as vesicles and then become ulcerous and contain large quantities of infectious HSV particles (Fig. 38.10). In primary infections, viral shedding can last 15 to 16 days, with new lesions continuing to form for up to 10 days after exposure. Asymptomatic viral shedding can continue for up to 1 year after resolution of the primary clinical presentation, increasing the risk of transmission to sexual partners. Lesions of primary genital herpes typically ulcerate and heal inward from the periphery without scarring within 3 weeks. Ulcers that form on dry surfaces (buttocks or thighs) heal more rapidly than those on mucocutaneous surfaces (vagina, cervix, glans of the penis). Women tend to have more severe disease caused by genital herpes infection, including constitutional symptoms and complications, compared with men. This disparity may be the result of the larger affected surface area of the female genital tract and the ability of HSV to spread more easily over the abundant moist surfaces.

After recovery from primary infection, HSV ascends along the sensory nerve roots to the dorsal root ganglion and establishes latency. Reactivation of the virus occurs on exposure to stressors, including extensive exposure to sunlight, menstruation, malnutrition, fatigue, anxiety, and subsequent viral infections. With reactivation, the virus travels from the dorsal root ganglion back down the nerve root to cause recurrent outbreaks of symptoms. Although clinical presentation is indistinguishable, recurrent disease caused by HSV-1 generally recurs less regularly compared with genital infections with HSV-2. Recurrent disease typically results in milder symptoms compared with those of the primary infection, and the lesions heal more quickly. Approximately 90% of patients with genital herpes have at least one recurrence during the first year after primary infection. The median recurrence rate for genital HSV-2 is four episodes per year, with an average of 50 days to first recurrence. Over time, the frequency of recurrence lessens.

The most serious complication of genital herpes is neonatal transmission. Neonatal infection with HSV usually occurs during delivery (85%) but can also occur congenitally (5%) or postnatally (10%). Symptoms of neonatal HSV disease acquired during delivery usually appear in the first 9 to 11 days of life. Exposure to vaginal secretions containing HSV can result in a variety of clinical manifestations, including localized disease of skin, eyes, and mucosa; central nervous system (CNS) involvement; or disseminated disease. The mortality rate for neonates with CNS or disseminated disease can be as high as 85%. Risk of transmission from mother to child during delivery is high (30% to 50%) among women who acquire the disease during the third trimester and is low (<1%) in women with a history of recurrent herpes at

Fig. 38.10 **A**, Vesicles of herpetic lesions on the penile shaft caused by herpes simplex virus 2. **B**, Maculopapular herpetic rash on the penile shaft and corona of the glans penis. After the vesicles break, tender ulcers may remain that might take 2 to 4 weeks to heal the first time they appear. (A, Courtesy Susan Lindsley, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA; B, Courtesy Dr. N. J. Flumara and Dr. Gavin Hart, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

term or who acquire genital HSV infection during the first half of pregnancy. It is thought that maternal antibodies from recurrent infections protect the neonate from serious disease. Other serious complications of genital HSV infection include corneal infection and fatal sporadic encephalitis in immunocompromised hosts.

Laboratory diagnosis

Viral isolation was the most common method for the diagnosis of HSV infections. The best specimens for culture are vesicle fluids collected with a syringe or swab. Cervical swabs and mucosal surface swabs are also acceptable specimens. Specimens for culture from mucocutaneous lesions must be taken as early as possible in the disease process. The likelihood that a herpetic lesion will produce a positive culture diminishes with each day after the appearance of the lesion. Specimens should be placed in viral transport medium, shipped cold, and not frozen. If crusting lesions are the only possible specimen for culture, vigorously collected specimens containing epithelial cells from the lesion help increase the sensitivity of culture. Viral samples can be stored at 4° C; however, specimens being kept for longer periods should be stored at –70° C.

HSV grows rapidly on numerous cell culture lines, and the cytopathic effect (CPE) in culture is usually seen within the first 24 hours in most cases, but some isolates can take as long as 14 days to develop a CPE. The most common cell lines used for viral culture include mink lung, rhabdomyosarcoma, MRC-5, HEp-2, and A549 cells. Infected cells develop intracellular granulations, enlarge, and then display intracellular inclusions (Fig. 38.11). Viral culture is a reliable method to detect HSV because it is highly specific and relatively inexpensive. However, the sensitivity ranges from 30% to 95%, depending on the stage of the lesion and whether it

Fig. 38.11 Culture results of a genital specimen inoculated into A549 cells. Cytopathic effects demonstrate rounded, swollen, refractile cells (unstained, $\times 100$). (Courtesy Bonnie Hill, Brooke Army Medical Center, San Antonio, TX.)

is a primary infection or recurrence. The sensitivity of viral culture is especially low for recurrent lesions.

Because of the low sensitivity of viral culture and because other viruses can mimic the CPE of HSV, confirmation using monoclonal antibodies against type-specific epitopes is recommended. The CDC recommends serotyping viral culture isolates to determine whether infection is caused by HSV-1 or HSV-2. Other available confirmatory tests include genetically engineered cell lines, EIAs, the enzyme-linked virus-inducible system (ELVIS; Diagnostics Hybrids, Athens, OH).

NAATs have generally replaced cell culture as the diagnostic method of choice because of their sensitivity, specificity,

and rapid results. NAATs are regarded as the most sensitive methods for direct detection of HSV. Depending on the gene targets, an assay can detect HSV-1 and HSV-2 or distinguish between HSV-1 and HSV-2. Examples include the MultiCode-RTx kit (Luminex, Austin, TX), ProbeTec HSV-Q^x test (BD Diagnostic Systems), and AmpliVue HSV 1 + 2 assay (Quidel, San Diego, CA).

Treatment

Genital herpes is a chronic, life-long viral infection for which there is no cure. Antiviral chemotherapy is widely used to treat mucocutaneous and genital herpes, offering some clinical benefits to most symptomatic patients. Clinical trials have demonstrated that acyclovir, valacyclovir, and famciclovir are effective antivirals for the treatment of genital herpes. These drugs can reduce the signs and symptoms of genital herpes when used to treat primary infection and recurrent episodes. No treatment currently exists that will eradicate latent virus or reduce the risk, frequency, or severity of recurrences after therapy is discontinued. Suppressive therapy can reduce the frequency of recurrences by 70% to 80% in patients who have more than six recurrences per year.

The safety and efficacy of suppressive therapy have been demonstrated in patients receiving daily therapy with acyclovir for up to 6 years and with valacyclovir or famciclovir for 1 year. Not only does daily therapy decrease the frequency and duration of recurrences, but it also limits viral shedding, reducing disease transmission rates. Clinicians also use suppressive therapy to prevent transmission of HSV from mother to child during delivery. Neonates exposed to HSV infection during delivery should be closely monitored for symptoms of disease. Treatment with intravenous (IV) antiviral chemotherapy can reduce the overall morbidity and mortality of neonatal herpes. The CDC recommends IV administration of acyclovir for treatment of neonatal herpes (20mg/kg body weight IV) every 8 hours for 21 days for disseminated and CNS disease or for 14 days for disease limited to skin and mucous membranes.

Case study

A 23-year-old homeless female patient addicted to crack cocaine is arrested during a drug raid and brought to jail. During her in-processing physical examination, she admits to routinely exchanging sex for drugs to maintain her drug habit. The health care provider notes a rash on the prisoner's palms and soles. Samples of the lesions are obtained, and spirochetes are identified through dark-field microscopy. A serum sample is also taken and submitted to the laboratory for rapid plasma reagin (RPR) screening and confirmational tests for syphilis.

Syphilis

Epidemiology

Syphilis is a genital ulcer disease caused by the spirochete *Treponema pallidum* subsp. *pallidum* (*T. pallidum*). *T. pallidum* is an obligate parasite of humans, with no other known animal hosts or environmental reservoirs. Despite the existence of effective prevention measures, such as barrier prophylaxis, and treatment options, syphilis remains a global problem, with an estimated 12 million people infected each year. The incidence of syphilis in the United States immediately following World War II was close to 500,000 cases per year. The number of reported infections decreased by 89.7% during the 1990s, and in 2000, the rate was the lowest since reporting began. Primary and secondary syphilis rates increased from 2001 to 2009, and the CDC reported 13,997 infections in 2009. In 2010, the overall rate of new syphilis infections decreased for the first time in 10 years, with 13,774 cases (4.5 cases per 100,000 people). However, the number of cases increased every year from 2011 to 2020 (Fig. 38.12). In 2020, 41,655 cases of primary and secondary syphilis and 133,945 cases of all stages of syphilis were reported in the United States. The rate of primary and secondary syphilis infections has increased almost every year since the historic low in 2000, increasing 6.8% during 2019–2020.

Fig. 38.12 Rates of reported cases of syphilis by stages of infection. (Modified from Centers for Disease Control and Prevention. [2020]. Sexually transmitted disease surveillance, 2020. Atlanta: Centers for Disease Control and Prevention.)

Not surprisingly, the incidence of congenital syphilis mimics the rate for primary and secondary syphilis. The average yearly rate of congenital syphilis decreased by 14.1% from 1996 to 2005, representing a total 74.2% decrease overall during that period. Unfortunately, the rate of congenital syphilis increased from 2006 to 2008, but it decreased to 334 cases in 2012. From 2013 to 2020, there was a steady increase, with 2148 cases reported in 2020.

Most reportable cases of syphilis occur in the western United States and in urban areas in other parts of the country. The CDC estimated that the proportion of primary and secondary syphilis cases attributable to MSM increased by 58% from 2000 to 2004. Beginning in 2005, the CDC required all state health departments to report the sex of partners of persons with syphilis. Data from the 44 states and the District of Columbia that provided information about the sex of sexual partners indicate that the highest percentage (53.5%) of primary and secondary syphilis cases in 2018 occurred in MSM. Most of these new infections are occurring in the young African American gay community.

Clinical manifestations

Syphilis is a multistage disease, with diverse and wide-ranging clinical manifestations. *T. pallidum* is an invasive organism that can enter the host through any site and initiate infection. There are four stages in the pathogenesis of syphilis: primary, secondary, latent (hidden), and tertiary syphilis. The incubation period from initial exposure to development of the primary **chancre** ranges from 10 to 90 days. Infection occurs when *T. pallidum* penetrates dermal microabrasions or intact mucous membranes, typically producing a single, painless, nonsuppurative lesion, called a *chancre*, at the site of inoculation (Fig. 38.13). Appearance of the initial chancre, usually in the anogenital region, signals primary syphilis. Moderate regional lymphadenopathy is associated with the primary stage. The chancre usually becomes indurated and will progress to ulceration but typically is not purulent. In some cases, syphilis occurs without a visible ulcer. The chancre has an indurated raised edge and is extremely infectious. The lesion will spontaneously heal in 3 to 6 weeks (but this can be as long as 12 weeks) if the patient does not receive antimicrobial therapy. The disappearance of the chancre does not signal an end to the infection.

Fig. 38.13 Chancres on the penile shaft resulting from a primary syphilitic infection caused by *Treponema pallidum*. Painless lesions are indurated with raised edges. (Courtesy M. Rein, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

Treponemes gain access to the bloodstream in untreated patients, and this spirochetemia is responsible for the signs and symptoms of secondary syphilis, which begin about 6 weeks to 6 months after infection. Clinical manifestations of secondary syphilis include, but are not limited to, rash, mucocutaneous lesions, and lymphadenopathy (Fig. 38.14). This is when the organisms are at their highest numbers. The hematogenous spread of the treponemes causes fever, lymphadenopathy, myalgia, and anorexia. Almost any organ can be involved in secondary syphilis. Signs of organ system involvement include hepatitis, osteitis, and keratitis. CNS involvement can also occur during the secondary phase. Most patients develop macular or papular skin lesions involving the trunk, soles of the feet, and palms. Fluid from these so-called *nickel-and-dime lesions* is extremely infectious. Another result of secondary syphilis is the appearance of **condylomata lata**, which are mucoid, wartlike growths (Fig. 38.15). These lesions

Fig. 38.14 Close-up view of keratotic lesions on the palms of a patient's hands caused by a secondary syphilitic infection. Each lesion is full of treponemes. (Courtesy Robert Sumpter, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

often occur in the perianal region but can occur in other moist regions of the body. Even without treatment, the symptoms of secondary syphilis disappear within a few weeks of onset, and the patient enters the latent phase. Patients are no longer infectious after secondary syphilis lesions heal; however, relapses occur in about 25% of untreated patients during the first year after infection.

Latent syphilis is divided into two stages: early latent and late latent syphilis. Patients are considered to have early latent syphilis during the first year after infection, whereas late latent syphilis is defined as asymptomatic infection lasting longer than 1 year or with an unknown duration. The serologic testing result during the late latent stage is positive, and the patient is asymptomatic. Sexual transmission of disease is unlikely during the latent period, but organisms may enter the bloodstream intermittently and can infect the developing fetus during pregnancy. Latent syphilis is characterized by cerebrospinal fluid (CSF) abnormalities in the absence of symptoms. Indicators include elevated protein levels, depressed glucose levels, and lymphocytic pleocytosis (the presence of WBCs in CSF).

Many untreated patients relapse during the first year of the latent period and will suffer a recurrence of the symptoms associated with secondary syphilis. Other patients may never relapse, and a third group of patients will experience tertiary syphilis. Tertiary syphilis is associated with immune sequelae of primary and secondary syphilis, rather than the direct presence of treponemes. These patients may develop neurologic symptoms, cardiovascular effects (e.g., aneurysm), or late benign syphilis. In the latter condition, the patient develops nonspecific granulomatous lesions, called **gummas** (Fig. 38.16). Gummas can occur in skin, bone, or viscera and cause a localized form of tissue and bone destruction. The lesions rarely resolve without appropriate antimicrobial therapy. The late stages of syphilis develop in about 15% of untreated patients and can occur decades after they initially acquired the disease.

T. pallidum can cross the placenta and cause congenital infection in neonates. Up to 40% of all infants infected while in the womb are stillborn or die shortly after birth. Therefore effective detection and prevention rely on routine serologic screening during the first prenatal visit. In areas in which risk

for congenital syphilis is high, additional serologic screening and obtaining a sexual history should occur at 28 weeks' gestation and on delivery. If the mother's test results indicate syphilis, antimicrobial agents are administered to treat her and the fetus. Infection across the placenta is most likely to occur during the primary or secondary stages of syphilis, but the fetus can be infected at any time during pregnancy.

Congenital syphilis is divided into two stages: early disease and late disease. At birth, neonates with early congenital syphilis usually develop symptoms 2 to 10 weeks after delivery and show signs of secondary syphilis, including failure to thrive, fever, collapse of the nasal bridge (saddle nose), watery nasal discharge, hepatosplenomegaly, jaundice, rash, condylomata lata, meningitis, and periostitis. Untreated children can go on to develop late congenital syphilis. These patients are asymptomatic at birth but can develop blindness, deafness, arthritis, bone and joint pain, deformed lower leg bones (saber shins), and abnormal notched and peg-shaped teeth (Hutchinson teeth) as young children.

Laboratory diagnosis

T. pallidum does not survive outside a mammalian host, and all attempts to propagate the organism continuously *in vitro* have been unsuccessful. Dark-field microscopy and DFA for *T. pallidum* (DFA-TP) examination of patient specimens are considered the definitive methods for diagnosing early syphilis from lesion exudates. Today, blood tests are more commonly performed. Antibodies produced in response to infection with *T. pallidum* are detectable during primary syphilis, and their levels continue to increase as the disease progresses to the secondary stage.

Serologic tests for the diagnosis of syphilis are divided into two general types: **nontreponemal antibody tests** and **treponemal antibody tests**. The nontreponemal antibody tests, such as the rapid plasma reagin (RPR) test, unheated serum reagin assay, toluidine red unheated serum test (TRUST), and Venereal Disease Research Laboratory (VDRL) test are used as screening tests and detect the presence of antibodies to cardiolipin and other lipoidal indicators of tissue damage. These tests are not highly specific but usually correlate with disease activity. Febrile infections, pregnancy, and autoimmune disorders may produce biologically false-positive reactions with nontreponemal tests. A fourfold increase in titer between acute-phase and convalescent-phase sera is necessary to demonstrate a clinically significant difference between two nontreponemal test results obtained by the same methods. Clinicians can use quantitative nonspecific tests to follow the efficacy of treatment because these antibody levels decrease and ultimately disappear with the successful treatment of syphilis.

Patients with reactive nontreponemal test results are then tested with assays using specific treponemal antigens to confirm the diagnosis. These confirmatory tests are specific treponemal antibody tests and include the EIAs, fluorescent treponemal antibody absorption (FTA-ABS), chemiluminescence immunoassays (CIAs), immunoblot, and *T. pallidum* particle agglutination (TP-PA) tests. The most common tests performed in the United States are the TP-PA test and EIAs. These help distinguish true- and false-positive nontreponemal test results and the diagnosis of late latent or tertiary syphilis. Treponemal antibody tests cannot be used to follow therapy because these antibodies do not disappear following the successful treatment of

Fig. 38.16 Gumma found on the nose of a patient with tertiary syphilitic *Treponema pallidum* infection. Without treatment, a chronic infection will begin to damage the internal organs, including the brain, nerves, eyes, heart, blood vessels, liver, bones, and joints. (Courtesy J. Pledger, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

the disease. Most patients remain seropositive for life, regardless of the treatment or its success; however, 15% to 25% of patients who received treatment early in the disease revert to being serologically nonreactive within 2 to 3 years.

The CDC reported on the results of reverse screening for syphilis by several large reference laboratories. Because of high test volume and availability of automatable treponemal EIAs and CIAs, these facilities were performing the treponemal antibody test as the screening assay and following up all reactive test results by using the nontreponemal antibody test as the confirmatory assay. Interestingly, it was noted that 56.7% of all reactive treponemal antibody results were non-reactive by the RPR test. Because of this notable discordance, the CDC recommended performing an additional, different treponemal antibody test (TP-PA) when the results from the first two tests do not match.

The diagnosis of congenital syphilis is complicated by the ability of maternal nontreponemal and treponemal IgG antibodies to cross the placenta. This passive transfer of antibodies makes serologic test interpretation in neonates difficult. To differentiate maternal antibody from the infant antibody to syphilis, an IgM-specific FTA-ABS test may be useful. Current testing recommendations suggest that infants born to mothers who have reactive serologic test results should be evaluated with a quantitative nontreponemal serologic test (RPR or VDRL) performed on infant serum. Confirmation of congenital syphilis includes clinician suspicion based on symptoms and history along with demonstration of treponemes in body tissues or fluids.

Treatment

The CDC recommends a single intramuscular dose of benzathine penicillin G for the treatment of primary and secondary syphilis. Penicillin therapy has been the mainstay of treatment for over 50 years because *T. pallidum* isolates appear to be uniformly susceptible to β -lactam drugs. Current guidelines suggest multiple doses of aqueous or procaine penicillin G for suspected cases of neurosyphilis. A single dose of penicillin G is not as effective as multiple doses because low levels of the drug are maintained in CSF. Ceftriaxone, amoxicillin, and ampicillin are also effective for the treatment of early syphilis.

For patients allergic to penicillin, the CDC recommends doxycycline (100 mg orally twice daily for 14 days) or tetracycline (500 mg four times daily for 14 days) as an alternative regimen. Tetracycline and doxycycline are not recommended during pregnancy because of cosmetic concerns regarding staining of fetal primary dentition. Pregnant patients who are allergic to penicillin should be desensitized and treated with penicillin. The use of macrolides, such as azithromycin and erythromycin, for the treatment of syphilis is not recommended because of reported resistance.

Chancroid

Epidemiology

Chancroid, or soft chancre, is an STI caused by the fastidious, gram-negative bacterium *Haemophilus ducreyi*. Chancroid is a major cause of genital ulcerative disease in Africa, Southeast Asia, the Caribbean, and Latin America, and it is of increasing concern in the United States because of its role as a potential

cofactor in the transmission of HIV. Because it is difficult to confirm *Haemophilus ducreyi* infections microbiologically, the global epidemiology of chancroid is poorly documented, although UNAIDS and the WHO estimate that the annual global incidence of chancroid is approximately 6 million cases. Studies from regions in which chancroid is endemic revealed that most cases of the disease occurred in patients with direct exposure to commercial sex workers.

The disease was endemic throughout many parts of the world well into the 20th century. The prevalence of chancroid decreased steadily in the developed world before the discovery of antimicrobial agents, largely because of a reduction in mass migrations and tighter regulation of the commercial sex industry. According to the CDC, reported cases of chancroid decreased steadily from 1987 to 2001, when 38 cases were reported in the United States. Since 2002, the number of cases has fluctuated, with a decreasing trend. Only three cases of chancroid were reported in 2018. This trend most likely reflects a decrease in the incidence of this disease; however, rates of infection may be underreported because *H. ducreyi* is very difficult to culture. Many patients with chancroid are also co-infected with *T. pallidum* or HSV.

Clinical manifestations

Chancroid is characterized by painful genital ulceration, inflammatory inguinal adenopathy, and bubo formation. The pathogen enters through microabrasions in skin after sexual intercourse. Human inoculation experiments demonstrated that a dose of one colony-forming unit will result in infection at 50% of inoculation sites. A tender erythematous papule develops at the site of infection 4 to 7 days after exposure before progressing to the pustular stage. Once the papule develops into a pustule, it will usually rupture 2 to 3 days later to form painful, shallow ulcers with granulomatous bases and purulent exudates. The chancroid usually develops on the external genitalia of men and women. The sites of infection in men include the prepuce, coronal sulcus, glans, and shaft; in women, the labia, clitoris, vaginal wall, and cervix can be involved. At first glance, chancroid ulcers appear similar to syphilitic chancres and herpetic lesions but can be differentiated. The chancroid is a painful lesion with ragged or uneven, soft edges and a gray to yellow purulent exudate compared with the painless chancre, which has a hard indurated edge, and the painful herpetic lesion, which starts out with vesicles that later burst to reveal clear fluid and develop yellow crusts. The chancroid ulcer may persist for weeks or months, with slow resolution in the absence of antimicrobial therapy.

Painful, tender inguinal lymphadenitis occurs in almost 50% of all patients with chancroid. Lymphadenopathy in these patients is usually unilateral and is more frequently observed in men. If left untreated, swollen lymph nodes can develop into fluctuant buboes (Fig. 38.17), which can rupture spontaneously if not drained. Extragenital manifestations of chancroid are rare, but lesions have been observed on the inner thighs, breasts, and fingers.

Laboratory diagnosis

Clinical evaluation and laboratory culture of *H. ducreyi* is considered the gold standard for the diagnosis of chancroid. Ulcer lesion material and/or bubo aspirate may be submitted

Fig. 38.17 Early chancroid lesions on the penis and groin, along with accompanying regional lymphadenopathy. Chancroid lesions are painful and have ragged or uneven edges. (Courtesy Dr. Pirozzi, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

Fig. 38.18 Direct Gram-stained smear microscopic examination reveals the presence of gram-negative coccobacilli indicative of a chancroid infection (×1000). (Courtesy Joe Miller and Dr. N.J. Fiumara, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

for direct smear examination and culture. Microscopically, *H. ducreyi* is a pleomorphic, gram-negative coccobacillus that occasionally occurs in characteristic chains or so-called *school of fish* formations (Fig. 38.18). However, Gram-stained smears alone are not sensitive or specific for the diagnosis of chancroid because the specimen often includes numerous bacterial contaminants.

H. ducreyi is extremely fastidious and requires nutritious media for growth. Some clinical isolates grow well on chocolate agar, but enriched media can increase culture sensitivity. Two commercially available varieties of enhanced media contain GC agar base, hemoglobin, IsoVitalax, and fetal calf serum, and another has Mueller-Hinton agar with chocolate horse blood and IsoVitalax. Most *H. ducreyi* strains grow well at 33° to 35° C in a 5% CO₂ atmosphere. It is critical that specimens be sent as quickly as possible to the laboratory for successful culture. Even with the optimal combination of

media and timely delivery to the laboratory, culture is only about 80% sensitive.

Testing methods that are alternatives to culture, such as PCR and immunoassays, are being developed to increase the sensitivity of chancroid diagnosis. Currently, no FDA-approved PCR assays are commercially available in the United States. Multiplex PCR assays specific for the causative agents of genital ulcer disease have been privately developed and are performed in a few laboratories that have completed validation studies. Preliminary studies indicate that these assays are more rapid and sensitive than culture. Serologic detection of chancroid has been demonstrated by EIAs that contain antibodies against *H. ducreyi* lipooligosaccharide and antigen detection using DFA, but these assays are not widely available and have cross-reactivity problems. Given the limitations of alternative testing methods, culture remains the primary diagnostic test performed by most microbiology laboratories for suspected cases of chancroid.

Treatment

Antimicrobial therapy for the treatment of patients with chancroid resolves the clinical symptoms, prevents transmission, and cures the disease. The CDC's 2015 sexually transmitted diseases treatment guidelines include a single oral dose of azithromycin, orally administered ciprofloxacin (twice daily for 3 days), orally administered erythromycin (three times daily for 7 days), or a single intramuscular dose of ceftriaxone. Patients with underlying immunosuppression or HIV infection and uncircumcised male patients should be carefully treated. Genital ulcers heal more slowly in these patients, and persistence of *H. ducreyi* in the lesions has been documented. In uncircumcised male patients, lesions under the foreskin also take longer to heal. Given the difficulty of culturing *H. ducreyi* and the limitation of sensitive testing methods, presumptive treatment for chancroid should be considered if HSV infection and syphilis are ruled out. Chancroid should also be considered if the patient lives in or has traveled to an endemic area or to an area with an ongoing outbreak.

Lymphogranuloma venereum

Epidemiology

LGV is an STI caused by serovars L1, L2, L2a, L2b, and L3 of the intracellular bacterium *C. trachomatis*. Compared with serovars A to K, LGV strains are more virulent in experimental animal models of infection and more invasive in humans. LGV rarely occurs in the United States and other industrialized countries. Most LGV infections occur in Africa, Southeast Asia, Central and South America, and the Caribbean countries. The prevalence of the disease is unclear because of difficulty in clearly distinguishing it from other causes of genital ulceration and bubo formation, such as chancroid. The actual number of cases in the United States is unknown. However, the CDC reported a cluster of cases among MSM occurring between August 2015 and April 2016 in Michigan.

Clinical manifestations

C. trachomatis serovars predominantly infect monocytes and macrophages, passing through the epithelial surface to regional lymph nodes and causing disseminated infection.

Clinical LGV has three stages: primary, secondary, and tertiary. The primary lesion produced by *C. trachomatis* usually presents as a small genital or rectal lesion, which ulcerates at the site of transmission. It is possible for a primary lesion to be absent, or it may simply go unnoticed in the urethra, vagina, or rectum. Symptoms typically occur after a 3- to 30-day incubation period following exposure. **Proctitis** (rectal inflammation) can occur as a primary manifestation of infection following direct inoculation of the rectal mucosa, and symptoms may arise within days of exposure.

The secondary stage of LGV involves the spread of *C. trachomatis* from the initial site of inoculation via the lymphatics to regional lymph nodes. This stage begins 2 to 6 weeks after the development of the initial lesion and primarily affects the inguinal lymph nodes. The most commonly noted manifestation is a very painful unilateral inguinal and/or femoral lymphadenopathy. Pressure from the inguinal ligament separating the groin lymph nodes gives rise to the groove sign, once believed to be diagnostic for LGV, but occurring in only 20% of cases (Fig. 38.19). Affected nodes can coalesce to form buboes, which may then ulcerate and discharge pus from multiple points.

The inguinal form of LGV is more common in men because lymphatic drainage from the penis is to the inguinal lymph nodes. In women, lymphatic drainage of the vagina and cervix is to the retroperitoneal lymph nodes. As a result of enlargement and suppuration of the perirectal and pelvic lymphatics, LGV commonly presents as backache in women, with initial lesions on the cervix and upper vagina, or presents in the rectal area in MSM who engage in receptive anal intercourse. Rectal involvement presents as an acute ulcerative proctitis with bloody purulent rectal discharge, pain, tenesmus, and constipation and may be misdiagnosed as ulcerative colitis.

Fig. 38.19 Presentation of lymphogranuloma venereum with bilateral inguinal lymphadenopathy that discharges purulent material (buboes). The inguinal ligament separates inguinal and femoral nodes to create the so-called groove sign. (From Habif, T. [2009]. *Clinical dermatology: a color guide to diagnosis and therapy* [5th ed.]. London: Mosby.)

Systemic symptoms, such as fever, malaise, and headache, can occur during the secondary stage of LGV. Infection with *C. trachomatis* (all serovars) is not restricted to the genital region. Submaxillary and cervical gland lymphadenitis can result from exposure to *C. trachomatis* organisms during oral sex. Ocular inoculation causes conjunctivitis along with preauricular lymphadenopathy.

In the tertiary stage of the disease, untreated infections can lead to chronic inflammation and destruction of affected tissues. Patients with untreated LGV proctitis may develop rectal damage, strictures, and, in women, rectovaginal fistulae. If LGV remains untreated, lesions caused by *C. trachomatis* often lead to fibrosis and granulomas. Fibrosis can lead to lymphatic obstruction, causing elephantiasis of the genitalia in men and women and esthiomene in women that results in a destructive, hypertrophic, granulomatous enlargement of the vulva and subsequent ulceration. Tertiary-stage sequelae do not typically disappear once antimicrobial therapy is initiated, and surgical intervention is required to correct many late complications, such as rectal stricture.

Laboratory diagnosis

The diagnosis of LGV is based on clinical presentation, epidemiologic information, and the exclusion of other causes of genital or rectal ulcers, inguinal lymphadenopathy, and/or proctitis. Isolation of *C. trachomatis* from specimens requires cell culture using HeLa-229 or McCoy cell lines. Cell culture used to be considered the gold standard, but the technique is no longer widely used because it is difficult to perform and has a low sensitivity.

Because of low sensitivity, DFA and EIA tests are not recommended for the direct detection of *Chlamydia*. Therefore NAATs have become the preferred diagnostic method for detecting genital *C. trachomatis* infections because of their high sensitivity and specificity. Many research articles have noted that self-collected specimens are almost as sensitive as health care provider-collected specimens. Depending on the manufacturer, urine specimens also yield similar sensitivities, thereby eliminating the more invasive specimen collection process.

Molecular identification is a two-step procedure. The first step confirms the presence of *C. trachomatis*. Available methods include PCR, strand displacement amplification, and transcription-mediated amplification. These assays are approved for the diagnosis of genital infections, and research shows high sensitivity and specificity in rectal infections, but they are not FDA-approved for rectal chlamydial infections. Specimens containing *C. trachomatis* advance to the second step for serovar determination by real-time or real-time quadruplex PCR assays. Detection of *C. trachomatis* in bubo or lymph node material by any of these diagnostic methods is highly suggestive of LGV, especially within an endemic area; however, detection of the organism in ulcer material can support the diagnosis only if the strain is identified by sequencing or typing assays.

Three serologic techniques for *C. trachomatis* infection are available: complement fixation, microimmunofluorescence, and EIA. Complement fixation and microimmunofluorescence titers greater than 1:64 along with high anti-MOMP antibodies indicating a positive result support LGV diagnosis in an appropriate clinical context. LGV serologic

test interpretation is not standardized, and *C. trachomatis* serovar-specific serologic tests are not widely available. Serology has a limited use in the diagnosis of *Chlamydia* infections.

Treatment

Current CDC treatment guidelines for LGV include the use of orally administered doxycycline twice daily for 21 days, or erythromycin orally four times a day for 21 days. A course of therapy lasting at least 3 weeks is recommended because of the deep tissue penetration by the organism. Doxycycline is not recommended for use in pregnant or lactating women. An alternative treatment recommended for these patients is erythromycin, four times daily for 21 days. Azithromycin may prove useful for treatment of LGV in pregnancy, but minimal clinical data are available on its effectiveness for the treatment of LGV. Anorectal LGV has an excellent prognosis if the disease is diagnosed and treated early. Delays in treatment can lead to serious complications, such as abscesses, fistulae, and rectal strictures. In settings without access to specific diagnostic LGV testing, the CDC recommends treating patients who present with symptoms consistent with LGV, such as proctitis, genital ulcer disease, or inguinal lymphadenopathy.

Patients with both LGV and HIV infection should receive the same treatment regimen as that for HIV-negative individuals. Prolonged antimicrobial therapy may be required for HIV-positive patients, and symptoms may resolve more slowly. Sexual contacts of patients in whom LGV has been diagnosed should be notified within 60 days of symptom onset to be evaluated and treated. Prompt treatment can prevent symptom development and lessens the risk of the original patient becoming reinfected. Sexual intercourse should be avoided until the course of treatment is completed and symptoms have disappeared completely.

Donovanosis

Epidemiology

Donovanosis, also known as **granuloma inguinale**, is a genital ulcerative disease caused by the intracellular, gram-negative bacterium *Klebsiella granulomatis* (formerly *Calymmatobacterium granulomatis*). The disease is rare in the United States but is endemic in some tropical and developing areas, including India, Papua New Guinea, central Australia, Brazil, and southern Africa. Ulcers are most common in uncircumcised men with poor standards of genital hygiene. Disseminated donovanosis may spread to bone and liver and is often associated with complications during pregnancy and cervical infection. Cases in the United States typically involve someone who is from or has recently traveled to an endemic region.

Clinical manifestations

Donovanosis is thought to be spread by direct contact with lesions during sexual activity; however, nonsexual transmission has been documented. Donovanosis often produces a firm papule or subcutaneous nodule that ulcerates at the primary site of inoculation. Ulcerative lesions usually develop in the genital region but may occur at oral, anal, or

other extragenital sites. Lesions frequently appear in warm, moist surfaces, such as the folds between the thighs, perianal region, scrotum, or labia. Local lymphadenopathy occurs, leading to ulcerative lesions developing in the skin overlying the infected lymph nodes. Four types of donovanosis have been described in the literature:

1. Ulcerogranulomatous—the most common type, with painless, beefy red ulcers that bleed to the touch and are well-defined, friable, nontender, and nonindurated with profuse granulation tissue (Fig. 38.20)
2. Hypertrophic (verrucous)—usually with a raised, irregular edge and sometimes completely dry
3. Necrotic—offensive-smelling ulcer causing tissue destruction; common in patients with long-standing donovanosis
4. Sclerotic or cicatricial—with fibrous or scar tissue

In men, donovanosis frequently affects the penis, scrotum, glans penis, and/or anus. In women, the disease primarily affects the labia minora, fourchette, and, less often, the cervix and upper genital tract. Pregnant women have a higher risk for developing disseminated donovanosis, with spread to bone and liver predominating. Extragenital exposure may result in ulceration of the lips, cheeks, and gums. If left untreated, the disease process may result in extensive destruction of the genitalia and spread to distant sites by autoinoculation. It is considered to be only mildly contagious; repeated exposure may be necessary for clinical infection to occur.

Laboratory diagnosis

Diagnosis of donovanosis is usually determined clinically based on a detailed history and physical examination findings of ulcerative lesions in a patient with sexual contact in an endemic region. Diagnosis can be confirmed by

Fig. 38.20 Progressively ulcerative, highly vascular, beefy red lesions caused by *Klebsiella granulomatis* (donovanosis). (Courtesy Joe Miller and Dr. T. Tabua, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

Fig. 38.21 Wright-stained smear of biopsy sample of granuloma inguinale lesion revealing Donovan bodies, encapsulated rods of *Klebsiella granulomatis* within macrophages ($\times 1000$). (From Rakel, R. E., & Rakel, D. P. (2011). *Textbook of family medicine* [8th ed.]. Philadelphia: Saunders.)

performing Giemsa or Wright stains of tissue and identifying characteristic intracellular **Donovan bodies** within macrophages (Fig. 38.21). Smears obtained directly from tissue or biopsy samples can be examined. Donovan bodies measure 0.5 to 0.7 mm $\times$ 1 to 1.5 mm in diameter and may or may not be encapsulated.

K. granulomatis is an extremely fastidious organism and cannot be grown on conventional bacteriologic media. It will only grow in eggs, peripheral blood mononuclear cells, and a few cell lines, so culture is beyond the capability of most clinical laboratories. PCR assays have been developed to detect *K. granulomatis*, but no FDA-approved test is commercially available. A DFA assay was developed using antigen derived from donovanosis lesions. These assays have low sensitivity for detecting early infection and are not widely available.

Treatment

Very few studies on donovanosis treatment have been reported in the literature. Effective treatment halts the progression of destructive ulcers, but therapy should continue until granulation and reepithelialization of the lesions occur. The CDC recommends azithromycin, taken orally once a week for 3 weeks, until all symptoms resolve. Alternative antimicrobials include doxycycline, ciprofloxacin, erythromycin, and trimethoprim-sulfamethoxazole. Doxycycline and ciprofloxacin are contraindicated in pregnant women. Pregnant and lactating women should be treated with erythromycin or azithromycin. Individuals with both donovanosis and HIV should receive the same treatment regimen as those who are HIV negative. Addition of an aminoglycoside should be considered to increase the chances of successful resolution. Patients should be followed up clinically until symptoms of the disease have resolved. Recurrence of symptoms can occur 6 to 18 months after symptom resolution, even after apparently effective therapy was completed. Sexual contacts within the 60 days preceding the onset of symptoms should be identified and examined for disease. Once the lesions have healed, extensive deformity and functional disability may require surgical repair.

Case check 38.4

In the United States, the three most common genital ulcer diseases are herpes, syphilis, and chancroid, with herpes being the most common. Infected individuals develop a latent infection, so recurrences may appear later. In the Case in Point, there is no mention of a genital ulcer disease, but in some cases, ulcers are not readily visible and may not be sought if there is no pain. This also stresses the need to obtain a detailed medical history and to ask appropriate questions, including about individual customs, to get a full health assessment for the patient.

Acquired immunodeficiency syndrome

Case study

A 21-year-old gay male patient presents to the local STD clinic with complaints of tenesmus, rectal discomfort, bloody stools, and a purulent discharge. There are also a few nonpainful ulcerative lesions noted around the anus. The patient's social history indicates that he has had multiple partners since a breakup with his boyfriend more than 6 months ago. He routinely chats with potential partners online to arrange anonymous encounters. He reports commonly participating in receptive anal intercourse and anilingus. His health care provider swabs the ulcers, takes a second swab from the rectum, and orders blood work for HIV screening. The following laboratory test results are discussed with the patient: molecular assay for *C. trachomatis* and *N. gonorrhoeae* was positive for *N. gonorrhoeae*; RPR test was positive; titration of 1:32, FTA-ABS test was positive; and HIV1/2 antigen/antibody immunoassay was negative. The patient received a diagnosis of concurrent gonorrhea and syphilis.

Causes

Human immunodeficiency virus (HIV) is a lentivirus in the family Retroviridae and is the causative agent of AIDS. It is a non-icosahedral, enveloped virus with two copies of a single-stranded RNA genome. HIV mainly targets CD4⁺ lymphocytes, which become depleted over time, leaving the body susceptible to many opportunistic infections because of the impaired immune system (Fig. 38.22). Individuals become infected with HIV through various routes of viral exposure—cervicovaginal, penile, rectal, oral, percutaneous, IV, or in utero.

To infect a cell, viral surface glycoproteins bind to receptors on the CD4⁺ lymphocyte, which allows the viral envelope to fuse with the cell plasma membrane. The viral contents are released into the cell, where the RNA genome is reverse-transcribed into DNA, transported to the cell's nucleus, and integrated into the host cell DNA as a provirus. The HIV provirus produces HIV proteins and enzymes to form new viral particles. These HIV particles are released by budding from the cell to infect other cells throughout the body.

The viral genome encodes a number of structural proteins (gag, pol, and env), regulatory proteins (tat and rev), and accessory proteins (vpu, vpr, vif, and nef). Structural proteins are necessary for viral replication because they are associated

Fig. 38.22 Colorized scanning electron micrograph of human immunodeficiency virus 1 virions (green) budding from a cultured lymphocyte (pink) ($\times 20,000$). (Courtesy C. Goldsmith, P. Feorino, E. L. Palmer, W. R. McManus, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

with the viral core (gag), polymerase (pol), and the viral envelope (env). Also, the three enzymes necessary for multiplication include a reverse transcriptase to transcribe viral RNA into DNA, an endonuclease that enables the DNA to be integrated into the host cell, and a protease that cleaves proteins to help viral maturation.

Epidemiology

Currently, there are two known types of HIV: HIV-1 and HIV-2. HIV-1 is the predominant virus worldwide, with estimates of almost 7000 persons becoming infected daily. HIV-2 is less pathogenic and geographically limited primarily to West Africa and European immigrants from West Africa. The AIDS pandemic began in the early 1980s, and in the beginning, the overwhelming majority of reported cases occurred in the male homosexual population. Other potential risk factors at that time included IV drug use, being of Haitian origin, and having hemophilia A and receiving blood transfusions. Federal health officials feared that tens of thousands of homosexual men had the acquired immune dysfunction, which they likened to an immunologic time bomb.

Initially, there was a rapid annual increase in the number of reported HIV infections and AIDS-related deaths. In the early years, the stigma of a positive test result was daunting; with few treatment options available, death was inevitable. To date, almost 33 million people worldwide have died from AIDS-related causes. When combination **highly active antiretroviral therapy (HAART)** gained widespread use, the number of deaths decreased, especially in developed countries. In 2019, there were 690,000 AIDS-related deaths, representing a 60% decrease since 2004. People infected with HIV are now surviving longer, thus increasing the overall number of people with HIV.

As of 2019, the WHO estimated that there are 1.65 million people newly infected and 38.0 million individuals worldwide with HIV. Approximately two thirds of these infected individuals reside in sub-Saharan Africa. Other areas of high infection prevalence are noted in several states from the former Soviet Union. In higher-income countries, such as the United States, Britain, and those in western Europe, the total

number of people with HIV continues to increase, largely because of access to better health care and HAART.

According to the CDC, approximately 1.2 million individuals currently have HIV infection in the United States, of whom approximately 14% are unaware that they are infected. Male homosexuals still develop most of the infections annually, especially in the African American population. However, in today's society, almost one third of all new HIV infections occur in heterosexuals engaging in risky behaviors. In 2018, African Americans accounted for approximately 42% of all new infections. Several outreach and educational awareness programs have been developed to promote frequent screening of individuals, especially those who are considered to be at high risk for infection (IV drug use, exchanging sex for drugs, unprotected sex, sex with multiple or anonymous partners, previous STIs). Although the percentage of infected and unaware persons is decreasing, screening and educational efforts must continue because these individuals are most likely to continue to spread the disease to further contacts.

Clinical manifestations

HIV infection can be considered a progressive disease noted by three specific phases: acute infection, clinically latent infection, and immunodeficiency (AIDS). HIV infection leads to gradual deterioration of the immune system over time as the virus continues to replicate and infect more cells, gradually decreasing the number of CD4⁺ T lymphocytes. The loss of these T cells leads to overwhelming opportunistic infections caused by numerous viruses (cytomegalovirus, varicella-zoster virus, HSV, and JC virus), bacteria (*Mycobacterium* and *Salmonella*), fungi (*Candida*, *Coccidioides*, *Histoplasma*, *Cryptococcus*, and *Pneumocystis*), and protozoa (*Cryptosporidia*, *Cystoisospora*, and *Toxoplasma*) that affect almost every organ system.

Certain serious and life-threatening diseases are termed *AIDS-defining illnesses* (Box 38.1), indicating that the patient has reached the advanced stage of HIV infection, that is, AIDS. As a public health measure for surveillance and reporting, HIV infection and disease have been defined and classified into five stages, 0 to 5 (Table 38.4). The current CDC classification system categorizes infection by increasing severity, all levels of which require laboratory-confirmed evidence of HIV infection in addition to the CD4⁺ T lymphocyte count or CD4⁺ percentage of total lymphocytes.

Acute infection

The acute primary HIV-1 infection is very difficult to recognize and diagnose because of the transient nature of the illness. Symptoms are noted in 40% to 80% of patients within 2 to 4 weeks after primary infection and resolve within 7 to 14 days. The symptoms overall are fairly nonspecific, resembling a mononucleosis-like syndrome. Individual symptoms commonly noted include fever, maculopapular rash, oral ulcers, lymphadenopathy, malaise, weight loss, arthralgia, pharyngitis, and night sweats. During this acute phase, plasma viral particle levels reach high levels of up to 100 million copies of HIV-1 RNA per milliliter of plasma. Additionally, viral particles are destroying CD4⁺ T lymphocytes and seeding lymphoid organs and other tissue reservoirs for widespread dissemination.

BOX 38.1 AIDS-defining conditions

- Bacterial infections, multiple or recurrent^a
- Candidiasis of bronchi, trachea, or lungs
- Candidiasis of esophagus^b
- Cervical cancer, invasive^c
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (>1 month's duration)
- Cytomegalovirus disease (other than liver, spleen, or lymph nodes), onset at age >1 month
- Cytomegalovirus retinitis (with loss of vision)^b
- Encephalopathy, HIV related
- Herpes simplex: chronic ulcers (>1 month's duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 month)
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (>1 month's duration)
- Kaposi sarcoma^b
- Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex^{a,b}
- Lymphoma, Burkitt (or equivalent term)
- Lymphoma, immunoblastic (or equivalent term)
- Lymphoma, primary, of brain
- *Mycobacterium avium* complex or *Mycobacterium kansasii*, disseminated or extrapulmonary^b
- *Mycobacterium tuberculosis* of any site, pulmonary,^{b,c} disseminated,^b or extrapulmonary^b
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary^b
- *Pneumocystis jirovecii* pneumonia^b
- Pneumonia, recurrent^{b,c}
- Progressive multifocal leukoencephalopathy
- *Salmonella* septicemia, recurrent
- Toxoplasmosis of brain, onset at age >1 month^b
- Wasting syndrome attributed to HIV

^aOnly among children <13 years of age.

^bCondition that might be diagnosed presumptively.

^cOnly among adults and adolescents >13 years of age.

AIDS, Acquired immunodeficiency syndrome; HIV, human immunodeficiency virus. Modified from Centers for Disease Control and Prevention. (2014). *Revised surveillance case definitions for HIV infection—United States, 2014*. Atlanta: Centers for Disease Control and Prevention. *MMWR Morbidity and Mortality Weekly Report*, 63, 1. Available at: <https://www.cdc.gov/mmwr/preview/mmwrhtml/rr6303a1.htm>.

Clinically latent infection

As the primary infection resolves, CD4⁺ T-cell counts increase while viral particle levels decrease and reach a steady-state level. During this stage, the virus is actively replicating in lymphoid tissue destroying large numbers of T cells. However, because T-cell production keeps pace with the number of T cells destroyed, immune function is intact, and the individual is asymptomatic. This asymptomatic period may last several years before the development of clinical immunodeficiency. The CD4⁺ T cell count gradually decreases while the virus continues to replicate and produces high titers of virus in affected tissues. This clinically latent period lasts approximately 10 years on average. Some patients are rapid progressors, developing AIDS within 1 to 2 years, as opposed to others considered long-term non-progressors, who may remain symptom-free for longer than 20 years. The rate of disease progression is dependent on host immune response, host genetic factors, characteristics of the infecting virus, and preventive therapies or lifestyle changes.

Progression to acquired immunodeficiency syndrome

The continued replication of HIV-1, coupled with the elimination of host immune cells, leads to deterioration of the immune system. At this point, the infected individual begins to develop one or more of the various AIDS-defining illnesses (see Box 38.1). Some of the most common AIDS-defining conditions (Fig. 38.23) include *Pneumocystis jirovecii* pneumonia, viral hepatitis, Kaposi sarcoma, oral candidiasis (thrush), and recurring bacterial pneumonias. In certain locations in which multidrug-resistant *Mycobacterium tuberculosis* is prevalent, a *syndemic* has been suggested, in which the convergence of two or more diseases act synergistically to magnify the burden of disease. HIV infection essentially alters the transmission

Table 38.4 Human immunodeficiency virus case definition, 2014^a

Stage	Laboratory evidence	Clinical evidence
0	Negative HIV test within 6 months of diagnosis	
1	Laboratory confirmation of HIV infection and CD4 ⁺ T lymphocyte count ≥500 cells/μL or CD4 ⁺ lymphocyte count >26% ^b	None required (no AIDS-defining condition)
2	Laboratory confirmation of HIV infection and CD4 ⁺ T lymphocyte count 200–499 cells/μL or CD4 ⁺ lymphocyte count 14–25% ^b	None required (no AIDS-defining condition)
3 (AIDS)	Laboratory confirmation of HIV infection and CD4 ⁺ T lymphocyte count <200 cells/μL or CD4 ⁺ lymphocyte count <14% ^b	Or documentation of an AIDS-defining condition with laboratory confirmation of HIV infection
Unknown	Laboratory confirmation of HIV infection and no information on CD4 ⁺ T lymphocyte count or percentage	And no information on presence of AIDS-defining condition

^aDefinitions are intended for public health surveillance only and not as a guide for clinical diagnosis.

^bStaging based primarily on CD4⁺ lymphocyte count; percentage considered if count is missing

AIDS, Acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

Modified from Centers for Disease Control and Prevention. (2014). *Revised surveillance case definitions for HIV infection—United States, 2014*. dynamics of tuberculosis, increasing the susceptibility and progression of disease.

Laboratory diagnosis

Multiple methods are available for diagnosing HIV infection with several available specimen types (blood, serum, plasma, urine, or even saliva). Generally accepted procedures rely on repeated positive screening results (EIA) followed by a more specific supplemental test for confirmation (IFA detection and NAAT). The initial IgG-sensitive EIAs (first and second generation) identified antibodies directed against HIV, which are not detectable until 4.5 to 6 weeks following initial infection. Newer screening assays detect the presence of anti-HIV IgG and IgM (third generation) or a combination of both anti-HIV antibodies as well as the p24 antigen (fourth generation). These latter-generation assays reduce the interval between infection and detection (window period) to within 2 weeks. This earlier detection can identify patients in the acute stage and potentially reduce the spread of disease. In August 2013, the FDA approved the first rapid test, the Determine HIV-1/2Ag/Ab Combo assay (Alere, Waltham, MA), that simultaneously detects HIV-1 p24 antigens as well as HIV-1 and HIV-2 antibodies. The test does not distinguish between HIV-1 and HIV-2 antibodies. In 2013,

the FDA also approved the first home testing kit, OraQuick in-home HIV test (OraSure Technologies, Bethlehem, PA). Saliva is the testing specimen, and antibodies to HIV can be detected in 20 to 40 minutes without sending the specimen to a laboratory for testing. Individuals are cautioned that positive results must be confirmed by laboratory testing.

Initial laboratory testing should employ an FDA-approved fourth-generation assay that detects HIV-1 and HIV-2 antibodies and HIV-1 p24 antigens (HIV1/2 antigen/antibody immunoassay). Reactive specimens should be tested using an FDA-approved supplemental antibody immunoassay to discriminate HIV-1 from HIV-2 antibodies. Specimens that test negative on the confirmatory assay should be subjected to an HIV-1 NAAT to assess them for possible acute HIV infection. This 2018 CDC recommended algorithm shortens the window period of HIV infection detection, accurately distinguishes between HIV-1 and HIV-2 infection, and reduces the turnaround time for confirmation of infection. The CDC does not have published guidelines for POC testing but does provide a recommended algorithm of a series of two different POC assays. If the first assay gives a positive result, a second assay using a different method or produced by a different manufacturer would confirm a probable infection. The patient should then be referred for HIV care. Recent studies demonstrate the efficacy of such an algorithm in rapidly

Fig. 38.23 Acquired immunodeficiency syndrome (AIDS)-defining illness. **A**, Pneumocystis pneumonia in a patient with human immunodeficiency virus (HIV) infection. This methenamine silver stain of lung tissue obtained from a biopsy of a patient with HIV infection showing cysts of *Pneumocystis jirovecii* ($\times 1000$). **B**, Patient with HIV infection with intraoral Kaposi sarcoma (KS) of the hard palate secondary to AIDS. KS lesions typically appear flat and purple-red in color but may be larger nodular growths. **C**, Patient with HIV infection with oral thrush caused by *Candida albicans*. (A, Courtesy Dr. Edwin P. Ewing, Jr., Centers for Disease Control and Prevention, Atlanta, GA; B, Courtesy Dr. Sol Silverman, Jr., Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA; C, Courtesy Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

diagnosing HIV infection and providing immediate initiation of counseling, HIV treatment, and determination of an individual therapeutic regimen.

Treatment

Once an infection is confirmed, the patient should see a health care provider to receive counseling and determine when to start HAART, even if he or she does not feel sick. Current treatment practice is to begin aggressive antiviral therapy when infection is diagnosed, even in the absence of symptoms. This helps achieve maximum benefit from the antiretroviral agents. Patients receive counseling to help them make lifestyle changes, if necessary, such as quitting smoking, reducing alcohol intake, and eliminating the use of illegal drugs. Patients are also encouraged to practice safe sex to avoid spreading HIV and acquiring other infectious agents.

Patients should be screened for tuberculosis, hepatitis, and other STIs so that appropriate prophylaxis (antimicrobial therapy or vaccination) can be provided to protect against infection. HIV-specific laboratory tests are requested to determine the patient's baseline viral load and CD4⁺ T cell count, as is genotypic or phenotypic testing of the patient's infecting HIV to determine appropriate HAART and overall efficacy.

Advances in HIV treatment have dramatically improved the prognosis for infected individuals. Before the era of HAART, a positive HIV test result implied an eventual downward spiral in the patient's health, culminating in full-blown AIDS and death. The goal of therapy is to prevent the immune system from being overwhelmed by the viral load and make opportunistic infections unlikely. HIV infection is treated with a combination of two or more drugs from different classes (Table 38.5). Since the development of HAART, the mortality rate in developed countries, where patients have excellent access to health care, has dropped substantially, so the population of patients with HIV increases annually. Infected individuals are leading more active lifestyles, with sometimes many years passing before the development of opportunistic infections and AIDS. This delay in progression has led many people to have a more casual attitude toward HIV infection status. Whether they are infected or not, they often continue their risky lifestyle behaviors, thinking that a cure will be found before they develop AIDS. Some individuals even consider an HIV-positive status as a mark of distinction.

Although HAART has been very effective overall, resistance to HAART is increasing because of nonadherence, which could become a significant health issue. Monitoring of patients may soon be required. As of 2022, five patients have reportedly been cured of HIV infection. These patients received bone marrow transplants from donor stem cells with a CCR5 mutation (CCR5Δ32). CCR5 is a coreceptor for HIV adhesion. Clearly, there is a need for more effective prevention programs in an effort to reduce the overall spread of disease.

Table 38.5 Recommended medicines for treatment of human immunodeficiency virus infection

Drug class	Drugs
Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs)	Abacavir, emtricitabine, lamivudine, tenofovir, zidovudine
Nonnucleoside reverse transcriptase inhibitors (NNRTIs)	Doravirine, etravirine, efavirenz, nevirapine, rilpivirine
Protease inhibitors (PIs)	Atazanavir, darunavir, fosamprenavir, ritonavir, saquinavir, tipranavir
Fusion inhibitors	Enfuvirtide
CCR5 antagonists	Maraviroc
Integrase strand transfer inhibitors	Cabotegravir, dolutegravir, raltegravir
Attachment inhibitor	Fostemasavir
Post-attachment inhibitor	Ibalizumab-uiyk

Case check 38.5

HIV infection is not exclusively an STI, but it is strongly recommended that when an individual is suspected or confirmed to have an STI, she or he should simultaneously be screened for HIV infection. This is because many of the risk factors for HIV infection are similar to those associated with other STIs. The Case in Point demonstrates the correct procedure to follow for HIV screening for the young man. It is imperative that individuals who engage in sexual activities, especially those who have sexual relations with multiple partners, be screened often and also when they change partners. Many individuals may be unknowingly infected and spread STDs to their contacts.

Other sexually transmitted diseases

Case study

A 16-year-old adolescent female patient presents to the pediatric clinic for a routine sports physical. During the checkup, her physician discusses common teenage sexual infections and diseases noted in her community. Although she is not sexually active, her physician discusses the effects of HPV infection, noting that teenagers are more susceptible to HPV infection (40%) and also more likely to develop precancerous growths, which, in turn, may develop into invasive cancer. Her physician provides information about a vaccine for protection against nine of the most common types of HPV that cause cervical cancer and genital warts and recommends that she receive the vaccine.

Genital warts

Epidemiology

Genital wart, caused by HPV, is the most common viral STI in the United States and the most common STI in individuals 24 years of age or younger. According to the CDC, in 2018, approximately 42.5 million people in the United States were infected with HPV. An estimated 13 million individuals become infected annually. The disease is so common that it is estimated that nearly all of the sexually active population contracts HPV at some point in their lives. Over 40 different genotypes of HPV infect the genital tract. They are distinguished into two groups. Certain genotypes cause various forms of cancer in the genital area, in particular in the cervix, while the second group causes genital warts. Two specific genotypes in this second group, types 6 and 11, are associated with approximately 90% of all genital wart cases. Anyone who is sexually active is at risk of infection.

Clinical manifestations

Humans are the only known reservoir for HPV. The virus affects skin and mucous membranes and causes development of warts in the moist and dry areas of the genitals, which can vary in size and shape. They are typically small bumps that can be raised or flat, single or in groups, small or large, and sometimes cauliflower shaped (Fig. 38.24). The manifestation of the cauliflower-shaped genital warts in moist regions is called **condylomata acuminata**. Genital locations include the vulva, vagina, anus, cervix, penis, scrotum, and groin or thigh. Infection is spread through intimate contact, usually during vaginal and anal sex. In MSM, anal

warts occur more often than genital warts. Depending on the genotype involved, infections could lead to cancer.

Diagnosis

Diagnosis of genital warts is clinically made on physical examination. Flat warts, which are not as visible, may be detected by applying a weak acetic acid solution to suspected areas of genital tissue; the solution causes infected areas to whiten, making them more visible. However, this is not a very sensitive means of diagnosis and is not recommended. Tissue biopsies may also be performed to confirm HPV infection.

Treatment

There is no permanent cure for HPV, and recurrences may be found on skin near the initial site. Several methods of treatment are available, including cryotherapy with liquid nitrogen, surgery (scissor excision, shave excision, curettage, laser, or electrosurgery), trichloroacetic acid, bichloroacetic acid, and various topical medications. In some cases, no therapy is used to see whether the warts will disappear on their own. Interferon- α can also be injected directly into the warts that have returned after removal using other traditional methods. OTC cures for warts should not be used near the genitals because severe irritation can occur. Sexual contact should be avoided until the warts have been treated and eliminated.

Lifestyle changes can reduce the risk of infection. Abstinence is the safest way to prevent an infection. Individuals should use safe sex measures, with barriers to prevent transmission, and limit the number of sexual partners. Additionally, women who have regular Pap tests can potentially detect infection earlier and get proper treatment. Three HPV vaccines

Fig. 38.24 **A**, Genital warts on the labia caused by human papillomavirus (HPV). **B**, Male patient with venereal warts (condylomata acuminata) in the anal region of the perineum caused by HPV. (A, Courtesy Joe Miller, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA; B, Courtesy Dr. Wiesner, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

are licensed in the United States: Gardasil 9 and Gardasil (Merck, Kenilworth, NJ), and Cervarix (GlaxoSmithKline, Philadelphia, PA). Since 2016, Gardasil 9 is the only one currently available. It targets the common genotypes for genital warts (HPV 6 and 11), the most common genotypes that cause cervical cancer (HPV 16 and 18) and five low-risk types for cancer (HPV 31, 33, 45, 52, and 58).

The vaccine is approved for children and adults 9 to 26 years of age. Although not 100% effective, studies have demonstrated that HPV vaccines reduce the risk of disease and may substantially decrease public STI clinic workloads. However, a national survey conducted in 2018 found that only 70% of girls and 66% of boys 13 to 17 years of age received one or more doses of the HPV vaccine.

Case check 38.6

Infections by certain HPV serotypes are associated with genital warts and cervical cancer. The Case in Point illustrates the need for the girlfriend to receive the vaccination to protect her against both forms of the disease. One commercially available vaccine is also approved for use in males, so the young man might require counseling to determine whether he should also receive the vaccination series. The girlfriend had a sore throat, and a quick inspection revealed only redness. This case illustrates the need for more thorough questioning and patient history. If the girlfriend recently engaged in oral sex with her boyfriend, submission of a throat swab for culture or molecular testing might be appropriate.

Viral hepatitis

Epidemiology

Viral **hepatitis** is a major global health problem. On exposure to a hepatitis virus, the liver becomes inflamed, interfering with liver functions and possibly leading to chronic effects, such as cirrhosis, hepatocellular cancer or liver failure. There are eight recognized hepatitis viruses that affect humans, of which three—hepatitis A virus (HAV), hepatitis B virus (HBV), and hepatitis C virus (HCV)—can be sexually transmitted. HAV can be spread via any sexual activity with an infected person and is not limited to fecal-oral contact but is more common in MSM. HBV is spread via contact with blood, semen, vaginal secretions, and other body fluids of an infected individual (Fig. 38.25). Sexual transmission is the most common method of HBV transmission in the United States. HCV is spread by contact with an infected person's blood; sexual transmission of HCV occurs at a much lower frequency and is more often reported among MSM.

Worldwide, the WHO estimates that 1.5 million new cases of HAV infection occur annually and that 2 billion individuals have been infected with HBV overall, of which almost 300 million are chronic carriers of HCV. In the United States, although thousands of cases of viral hepatitis are reported to the CDC each year, an even larger number of cases are silent or go undiagnosed. According to the CDC, there are approximately 24,900 new HAV infections, 22,600 new HBV infections, and 50,300 new HCV infections each year. Of the infectious

Fig. 38.25 Digitally colored transmission electron micrograph of hepatitis B virions. The large round virions are known as *Dane particles* ($\times 1,000,000$). (Courtesy Dr. Erskine Palmer, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

diseases, hepatitis is considered a “silent killer” because it is often misdiagnosed and largely remains unrecognized by those infected. Worldwide, it claims three times more lives compared with HIV infection.

Clinical manifestations

The clinical manifestations of viral hepatitis are all similar, but many acutely infected patients are often asymptomatic, or their symptoms are so mild and self-limiting that they are hard to recognize. When symptoms are present, patients experience a short, mild, flulike illness, along with fatigue, nausea, vomiting, and diarrhea. Over time, they may recognize loss of appetite, unintentional weight loss, and abdominal pain. The hallmark feature of hepatitis is jaundice, a condition in which the patient's skin and the whites of the eyes appear yellow (Fig. 38.26). Their urine has a darker yellow coloration and their stools appear pale or clay colored.

Diagnosis

Initially, screening tests are performed to diagnose infection. An acute hepatitis panel is ordered, which typically includes tests for IgM anti-HAV, IgM antibody against hepatitis B core (anti-HBc), hepatitis B surface antigen (HBsAg), and anti-HCV antibody and HCV RNA. Presence of IgM anti-HAV is diagnostic for HAV infection. HBV testing relies primarily on two tests: detection of anti-HBc and detection of HBsAg. Antibodies developed against the core means that a patient has been previously infected with HBV. Detection of surface antigen indicates that HBV virions are circulating throughout the patient's bloodstream. In patients infected with HCV, HCV RNA is detectable before the appearance of anti-HCV. Additional serologic tests are used to identify the status of infection for HBV or HCV, such as acute or chronic infection, or whether or not an individual was previously vaccinated against HBV. Molecular testing determines the presence of viral nucleic acid and can be used as a confirmatory test for HCV infection. Viral load testing for HBV or HCV is intended to monitor the efficacy of antiviral therapy.

Fig. 38.26 Patient infected by hepatitis A virus with icterus, or jaundice of the conjunctivae and facial skin. (Courtesy Dr. Thomas F. Sellers, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

Treatment

There is no specific treatment for HAV infection. Patients develop an acute infection, which is typically self-limiting and requires only supportive therapy. A vaccine against HAV is available and is recommended for those at greatest risk of disease. Acute infections with HBV are treated with supportive therapy. Chronic HBV infection and HCV infection are treated with antiviral agents. A vaccine against HBV is available, but there is none to protect against HCV infection. Chronic infections with HBV are treated with different antivirals, usually Interferon- α 2a (Roche, Switzerland) lamivudine, adefovir, telbivudine, tenofovir, or enfecavir. Liver transplantation may be an option for patients with severely damaged livers. Approximately 5% of all adults with HBV infection develop a chronic form of hepatitis, whereas younger children who are infected have a much greater rate of chronicity. For HCV infection, the Infectious Diseases Society of America recommends treatment with glecaprevir (8 weeks) or sofosbuvir (12 weeks). Approximately 90% of patients infected with HCV can be cured with therapy. In either case, patients with chronic infection require medical evaluation and regular monitoring of viral load to determine whether disease is progressing and to identify liver damage or hepatocellular carcinoma.

Pelvic inflammatory disease

Epidemiology

PID is a group of diseases affecting the female reproductive organs. It is a common complication of cervicitis in women who have mainly acquired the bacterial STIs chlamydia and gonorrhea. Annually, more than 1 million women are estimated to develop PID, and of these, over 100,000 may become infertile. PID develops as bacteria ascend the female genital tract into the reproductive organs. Sexually active women of childbearing age and women younger than 25 years of age are generally at the greatest risk of developing PID. Several risk factors for developing PID include having

multiple partners, frequent douching, and use of an intra-uterine device as a means of contraception. Previous episodes of disease also increase the risk of PID and further complications.

Clinical manifestations

The definition of PID is vague. It can be a conglomeration of several diseases of the female upper genital tract, such as endometriosis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. Disease can range from asymptomatic to severe. The full complement of commonly recognized symptoms of lower abdominal pain, fever, vaginal discharge, painful intercourse, pain on urination, and irregular menstrual bleeding should alert the health care provider to check for evidence of gonorrhea or chlamydia. Because symptoms may be vague and nonspecific, it has been estimated that PID goes unrecognized about two thirds of the time, leading to multiple complications caused by permanent damage to the reproductive organs.

Diagnosis

PID is very difficult to diagnose because of the absence of specific symptoms. There are no specific tests for PID, so the health care provider must usually make the diagnosis on the basis of physical examination and the clinical findings described earlier. Laboratory tests should be ordered to confirm infection with causative agents. Endometrial biopsy, transvaginal sonography, magnetic resonance imaging, or laparoscopy can also be used to ascertain the presence of findings consistent with PID. PID causes scarring in the reproductive organs, leading to serious complications, including chronic pelvic pain, infertility, ectopic pregnancy, and, in rare cases, spreading of the disease to the peritoneum and formation of scar tissue on the liver (Fitz-Hugh–Curtis syndrome).

PID can be prevented by adopting risk reduction methods. Abstinence or changes in social behavior and use of barrier methods all help decrease the probability of infection. When women identify any abnormal changes or recognize a potential infection, they should see their primary care provider immediately. The CDC recommends annual screening for all sexually active women 25 years of age and younger, all women in high-risk groups (e.g., multiple partners), and all pregnant women. The military recommends screening women for chlamydia at the entry level and until 25 years of age to reduce the level of PID in its female service members. Individuals with positive confirmed results can then be treated immediately, and their partners can be treated as well to reduce the risk of disease spread. Sexually active women experiencing pelvic or abdominal pain without an identifiable cause or demonstrating cervical motion, uterine tenderness, or adnexal tenderness should receive treatment.

Treatment

PID is treated with antimicrobial agents that are active against the specific causative organisms. Broad-spectrum

Fig. 38.27 Lesions of molluscum contagiosum on the leg and buttocks of a patient. These lesions appear as raised, pearlike papules or nodules that become umbilicated as they mature. (From Habif, T. [2009]. *Clinical dermatology: a color guide to diagnosis and therapy* [5th ed.]. London: Mosby.)

antimicrobials are used in an effort to promote action against multiple infectious agents. The regimen should include agents active against *N. gonorrhoeae* and *C. trachomatis*. Patients should be monitored after treatment to ensure treatment effectiveness. In severe cases, patients may need to be hospitalized for therapy.

Molluscum contagiosum

Molluscum contagiosum is a common skin disease caused by the molluscum contagiosum virus. This poxvirus can easily be spread through direct skin-to-skin contact or through contact with contaminated objects. It is considered an STI when found in the genital area. It is a common manifestation in patients with HIV infection and may signal immunosuppression. A common symptom is a small umbilicated papule that can become red and inflamed (Fig. 38.27). These papules can be easily removed when scratched or rubbed, thus spreading infection to other areas of the body. Diagnosis is clinical and can be confirmed by microscopic analysis. Treatment involves removal of the papules by scraping, freezing, or laser therapy. Avoidance of sexual contact is recommended until the infection has completely resolved.

In July 2022, monkeypox, a virus related to molluscum contagiosum virus, was declared a Public Health Emergency of International Concern by the WHO. In their August 7, 2022 report, 27,814 laboratory confirmed cases and 11 deaths were reported in 89 countries or territories. The United States reported about 11,000 cases at the same time. MSM seem to be at greatest risk for infection. This virus is spread by intimate contact as well as by contact with respiratory secretions and inanimate objects. Patients can present with a rash that may be located on or near the genitals (penis, testicles, labia, and vagina) or anus and could be on other areas like the hands, feet, chest, face, or mouth.

Epididymitis

Epididymitis is inflammation of the epididymis affecting men, usually those 19 to 35 years of age. This is generally a complication of chlamydia or gonorrhea. Common signs and symptoms include scrotal inflammation, testicular pain and tenderness, pain on urination or intercourse, chills and fever, lymphadenopathy, penile discharge, or blood in semen. Men who engage in high-risk sexual behaviors and have previously had STIs are at great risk of developing this condition. Diagnosis is based on clinical findings and Gram-stained smears of urethral secretions, positive leukocyte esterase urine test, or >10 WBCs per high-power field. Antimicrobial agents are administered for the confirmed infectious agent.

Proctitis

Proctitis is an inflammation of the rectal lining and is most common in those who engage in anal or oral-anal intercourse. Proctitis is mainly caused by the STIs chlamydia, gonorrhea, syphilis, and HSV infections. Symptoms include rectal bleeding, mucus passage, anal and rectal pain, and pain with bowel movements. When patients present to the health care provider for these complaints, additional STI screening should be performed. Treatment with antibacterial or antiviral agents can then be provided on the basis of the confirmed infectious agent.

POINTS TO REMEMBER

- STIs are caused by a wide variety and diverse group of infectious agents, including bacteria, viruses, protozoa, epizoa, and fungi.
- Many patients can have concurrent STI-related organisms. Therefore it is recommended to perform an HIV test on all patients suspected of having an STI.
- Syphilis testing requires positive nontreponemal and treponemal test results before infection is confirmed. Some facilities may perform the tests in reverse order.
- Clinical manifestations and presentations of the diseases are varied; some may be described as exudative, while others produce non-exudative lesions.
- Some STIs are asymptomatic.
- STIs are the main preventable cause of infertility in women.
- The epidemiology and pathogenesis of each infection may serve as useful tools in providing guidance with regard to specimen collection, transport, and handling, as well as methods for identification.
- The method and site of collection, quality of the clinical specimen, and clinical presentation are all important factors to consider when determining the causative agent of STIs.
- Molecular testing methods demonstrate increasing sensitivity of detection. By using noninvasive sampling, such as voided urine, more patients and contacts will present for screening assays, with the potential to reduce the sequelae of long-term infection through earlier treatment.
- HAART, when properly prescribed and used, can improve the quality of life and increase the longevity of those infected with HIV.

LEARNING ASSESSMENT QUESTIONS

1. What are the signs and symptoms and long-term effects of pelvic inflammatory disease (PID)?
2. What are the different causes of vulvovaginitis and how can they be distinguished clinically?
3. Why is it important to trace contacts of sexual partners of an individual with a diagnosis of a sexually transmitted infection (STI)?
4. Why is it important to screen for additional STIs in addition to that for which the patient is presenting?
5. What are the screening and confirmatory tests that aid in the diagnosis of STIs?
6. Which methods of prevention can be undertaken to reduce the overall spread of STIs?
7. What are the differences in clinical presentations and causes of chancroid and syphilitic chancre?
8. How has the advent of molecular testing advanced the detection of various STIs?
9. What are the distinguishing characteristics between gonococcal urethritis and nongonococcal urethritis (NGU)?
10. What genotypes are used in the Gardasil 9-valent human papillomavirus (9vHPV) vaccine and for what purpose?
11. Once HIV infection has been confirmed in an individual, which tests must be performed as these patients are managed?
12. Why are infections with hepatitis B virus (HBC) and hepatitis C virus (HCV) also listed as STIs?
13. Which important features allow herpesviruses (HPVs) to become latent infections?
14. For several years, the reported syphilis infection rates were declining, but now syphilis is beginning to make a comeback in the gay community. What could be causing this?
15. Some strains of *N. gonorrhoeae* have shown resistance toward penicillins, cephalosporins, fluoroquinolones, and some macrolides. What effects will this have on potential treatment regimens in the future? How may this affect screening tests for patients with probable gonorrhea infections?

Infections in special populations

Paula C. Mister and Donald C. Lehman

CHAPTER OUTLINE

Healthcare-associated infections, 976
Ventilator-associated pneumonia, 976
Malignancy, 977
 Infections in patients with neutropenia, 977
 Infections in patients with cancer, 977
 Infections in patients with Hodgkin disease, 978
Acquired immunodeficiency syndrome, 979
Complement deficiency, 979
Burns, 979
Organ transplantation, 979
Postsplenectomy sepsis, 980
Cystic fibrosis, 980
Diabetes, 981
Aging, 981
Pregnancy, the fetus, and the neonate, 981
Bibliography, 982

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Describe the various conditions that compromise the host's immune status.
2. Discuss the various infections that occur in each population.
3. Determine the risk factors associated with each condition.
4. Associate the various infectious agents that affect special populations with the conditions that predispose these patients to a specific infection.

KEY TERMS

Acquired immunodeficiency syndrome (AIDS)
Adaptive immune response
Cell-mediated immunity (CMI)

Complement
Congenital infections
Endogenous
Exogenous

Granulocytopenia
Healthcare-associated infection (HAI)
Hodgkin disease (HD)
Human immunodeficiency virus (HIV)
Humoral-mediated immunity (HMI)
Immunocompetent
Immunocompromised
Immunosenescence
Immunosuppression
Innate immune response
Neutropenia
Opportunistic
Perinatal
Postsplenectomy
Septicemia

Case in point

A 32-year-old female patient was vacationing out of town when she was involved in a serious car accident. She had extensive bruising on her abdominal region. She was sent by Medevac helicopter to a trauma hospital, where an emergency splenectomy was performed. Surgery and postoperative recovery were uneventful, and the patient was discharged and returned home. Two weeks later, the patient had flulike symptoms, such as fever, malaise, epigastric discomfort, shortness of breath, and nonproductive cough. She was rushed to the hospital closest to her home. The attending health care provider noted a large scar above the patient's abdomen and immediately ordered laboratory tests. She was admitted to the hospital, and laboratory tests suggested that the patient had sepsis. Cultures of her blood and sputum grew *Streptococcus pneumoniae*.

Issues to consider

After reading the patient's case history, consider:

- Characteristics of the organism causing the infections
- Risk factors for acquisition of the organism
- Risk factor that made the patient immunocompromised
- Opportunistic organisms associated with immunosuppressed patients

The presence of certain types of underlying disease can make people more susceptible to infection. People can also be more susceptible to infection as a result of being very young

or very old, pregnancy, malnutrition, or trauma. All of these situations have in common some form of **immunosuppression** that makes the host more susceptible to infections. The organisms found in these situations are often **opportunistic** organisms. Opportunistic organisms are those that typically do not cause disease in an **immunocompetent** host. Bacteria, fungi, parasites, and viruses can all cause opportunistic infections. Bacteria, such as the normal skin microbiota (e.g., *Corynebacterium*), which are often regarded as skin culture contaminants from immunocompetent patients, might need to be fully identified, and an antimicrobial susceptibility test might need to be performed when bacteria are isolated from immunocompromised patients. Table 39.1 lists the major organisms isolated from immunocompromised hosts.

Many of the organisms listed in Table 39.1 are common in the environment or are members of the host's normal microbiota. Thus opportunistic infections can have an **endogenous** or **exogenous** source. An endogenous infection occurs when a member of the host microbiota invades a body site where it is not normally found and causes disease. For example, viridans streptococci, normally found in the oral cavity, can gain access to the bloodstream and cause endocarditis when the patient has poor dental hygiene or when a dental procedure that disrupts the normal mucous membrane barrier is performed. In an exogenous infection, an organism present in the environment or another source, such as another person, enters the body through inhalation, ingestion, or traumatic inoculation and causes disease. For example, fungal conidia present in the soil are inhaled and may cause a respiratory tract infection.

The normal host immune response, whether it is non-specific barriers to infection such as intact skin and mucous membranes, the **innate immune response** of which macrophages and neutrophils are a major part, or the **adaptive immune response** in which B lymphocytes and T lymphocytes are active, is usually able to eliminate most of the organisms. When one or more parts of the immune response are deficient, however, organisms that are normally cleared start to proliferate and cause disease.

The term **immunocompromised** is used to describe patients who have a disease or condition that affects the immune system, making them highly predisposed to infections by various opportunistic bacterial, fungal, parasitic, and viral pathogens. The number of immunocompromised patients has increased steadily during the past 30 years, reflecting increased use of immunosuppressive therapy, instrumentation, and organ transplantation. Unfortunately, the potential gain in years of useful life for many patients through successful management and treatment of diseases can be offset by serious adverse effects on the immune system. As a result, infection, rather than the primary illness, becomes the leading cause of death in immunocompromised patients.

The primary predisposing factor in these patient populations is the presence of underlying disease that affects host defense mechanisms. Examples of compromised defense mechanisms include the following:

- Leukocyte number or function, as in aplastic anemia and leukemia
- Humoral- and cell-mediated immune functions, as in B-cell and T-cell abnormalities
- Reticuloendothelial system function, as in splenectomized patients

Table 39.1 Opportunistic pathogens most often identified in the compromised host

Bacteria	<i>Staphylococcus aureus</i> <i>Staphylococcus</i> spp., coagulase negative <i>Streptococcus pneumoniae</i> <i>Streptococcus</i> spp., viridans group <i>Pseudomonas aeruginosa</i> <i>Escherichia coli</i> <i>Klebsiella pneumoniae</i> <i>Salmonella</i> spp. <i>Serratia</i> spp. <i>Burkholderia</i> spp. <i>Acinetobacter</i> sp. <i>Stenotrophomonas</i> sp. <i>Haemophilus influenzae</i> <i>Legionella pneumophila</i> <i>Nocardia</i> spp. <i>Listeria monocytogenes</i> <i>Clostridioides difficile</i> <i>Mycobacterium tuberculosis</i> <i>Mycobacterium avium</i> complex and other nontuberculous mycobacteria
Parasites	<i>Toxoplasma gondii</i> <i>Strongyloides stercoralis</i> <i>Cryptosporidium</i> Microsporidia
Fungi	<i>Candida</i> spp. <i>Aspergillus</i> spp. <i>Pneumocystis jirovecii</i> <i>Cryptococcus neoformans</i> <i>Histoplasma capsulatum</i> <i>Fusarium</i> Mucormycoses (e.g., <i>Absidia</i> , <i>Mucor</i> , <i>Rhizopus</i>) Phaeohyphomycoses (e.g., <i>Alternaria</i> , <i>Curvularia</i> , <i>Exophiala</i>)
Viruses	Herpes simplex virus Varicella-zoster virus Cytomegalovirus Epstein-Barr virus Hepatitis B virus Adenovirus Papovaviruses Enteroviruses Influenza virus

Other underlying factors include burns, diabetes mellitus, renal failure, and autoimmune diseases. Table 39.2 summarizes the various conditions that compromise the host's immune status and the pathogens usually encountered in infections associated with them. Infection with **human immunodeficiency virus (HIV)** and immunosuppressive therapy, such as chemotherapy and radiation

Table 39.2 Organisms associated with compromised patients

Immune status	Examples of conditions	Commonly encountered pathogen(s)
Reduced leukocyte number or function	Myelocytic leukemia Chronic granulomatous disease Granulocytopenia Acidosis Burns	<i>Staphylococcus</i> spp. <i>Serratia</i> spp. <i>Pseudomonas</i> spp. <i>Candida</i> spp. <i>Aspergillus</i> spp. <i>Nocardia</i> spp. <i>Legionella</i> spp. <i>Mycobacterium</i> spp.
Reduced humoral-mediated immune response and complement deficits	Lymphocytic leukemia Multiple myeloma Nephrosis Antimetabolite therapy Hypogammaglobulinemia	<i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i> <i>Streptococcus pyogenes</i> <i>Pseudomonas</i> spp. <i>Pneumocystis jirovecii</i> Enteroviruses
Reduced cell-mediated immune response	Hodgkin disease Steroid therapy Uremia Antimetabolite therapy Acquired immunodeficiency syndrome Malnutrition	<i>Mycobacterium</i> spp. <i>Candida</i> spp. <i>Coccidioides immitis</i> <i>Histoplasma capsulatum</i> <i>Blastomyces dermatitidis</i> <i>Pneumocystis jirovecii</i> <i>Cryptococcus neoformans</i> <i>Cryptosporidium</i> Herpesviruses Adenoviruses Cytomegalovirus <i>Toxoplasma gondii</i> <i>Legionella</i> spp.
Reduced reticuloendothelial system function	Splenectomy Chronic hemolysis	<i>Streptococcus pneumoniae</i> <i>Salmonella</i> spp.

Modified from Drew, W. L. (2004). Infections in the immunocompromised patient. In K. J. Ryan & C. G. Ray (Eds.), *Sherris medical microbiology: an introduction to infectious diseases* (4th ed.). New York: McGraw-Hill.

therapy, particularly in organ transplant recipients, frequently lead to an immunocompromised condition. Secondary factors that facilitate infection include the use of invasive devices, such as indwelling intravenous (IV) catheters that breach the usual skin and mucosal protective barriers and introduce organisms into the bloodstream. One or a combination of any of these underlying conditions leaves a person less able to cope with infections.

Healthcare-associated infections

Hospitalized patients are at risk for several different types of infections for a variety of reasons, including being immunocompromised and undergoing invasive procedures. Collectively, these infections are referred to as **healthcare-associated infections (HAIs)** or *nosocomial infections*. A few of these infections are discussed separately in this chapter, such as ventilator-associated pneumonia (VAP). Central line-associated bloodstream infections, catheter-associated urinary tract infections, surgical site infections, and *Clostridioides difficile*-associated diarrheal disease are other examples. The risk of developing an HAI differs depending on the patient's immune status, overall health, medical conditions, and the procedures he or she is undergoing.

According to 2019 data from the Centers for Disease Control and Prevention (CDC), approximately 1 in 31 hospitalized patients develops at least one HAI. In 2002, it was estimated that 1.7 million HAIs occurred, with almost 100,000 deaths.

By 2015, there were 687,000 documented HAIs, with 72,000 deaths—a rate that, although still very high, was a significant improvement. Most HAI deaths are attributed to pneumonia and bloodstream infections. The most common organisms causing HAIs include *C. difficile* (70% of gastrointestinal [GI] infections), *S. aureus* (methicillin-susceptible *S. aureus* [MSSA] and methicillin-resistant *S. aureus* [MRSA]), enterococci (including vancomycin-resistant enterococci [VRE]), members of the Enterobacterales (particularly *Escherichia coli* and *Klebsiella* spp.), and *Legionella* spp. in cases of hospital-acquired pneumonia. Percentages of these pathogens depend on the geographic location and the type of facility (i.e., hospital or nursing home). Many of these isolates exhibit multidrug resistance. MRSA is the most common of these, but there has been a steady, worrisome increase in the past 10 years in the isolation of multidrug-resistant (MDR) gram-negative bacilli, including extended-spectrum β -lactamase (ESBL)-producing and carbapenem-resistant Enterobacterales. The good news is that overall, HAIs have dramatically decreased and continue to decrease slowly but steadily, with the implementation of specific infection control measures.

Ventilator-associated pneumonia

VAP is a nosocomial pneumonia that occurs in patients who have been on a mechanical respirator for more than 48 hours. It is the most common life-threatening nosocomial infection

in intensive care units. In 2019, the CDC HAI Progress Report listed a total of 24,724 ventilator associated events. Being on a mechanical ventilator substantially increases the risk of developing hospital-acquired pneumonia. VAP is estimated to occur in 5% to 67% of mechanically ventilated patients, depending on criteria used. In the United States, the incidence of VAP ranges between 2 and 16 episodes per 1000 ventilator days. As a result of aggressive preventive strategies, the mortality rate from VAP, which historically ranged from 33% to 50%, decreased in 2017 to 5.8% in early-onset VAP and 10.6% in late-onset VAP.

Signs of VAP include fever, white blood cell counts greater than $12 \times 10^9/\text{mL}$, and appearance of new or progressive pulmonary infiltrates or purulent tracheobronchial secretions. Although no gold standard exists, the diagnosis of VAP is usually made by using a combination of clinical, physiologic, radiologic, and microbiological evidence. The American Thoracic Society and the Infectious Diseases Society of America 2016 guidelines recommend obtaining noninvasive lower respiratory tract samples (e.g., endotracheal aspirates) for semi-quantitative microbiology culture. Collection of at least two sets of blood cultures may be helpful in determining the cause of the VAP in a febrile patient if the results of the cultures are positive. Rapid tests from additional types of specimens, such as urine for *Legionella* and *S. pneumoniae* antigens, serum for galactomannan or β -D-glucan for *Aspergillus*, and nasal specimens for respiratory syncytial virus (RSV) antigen, can be performed as well.

Colonization of endotracheal tubes with microbiota, usually environmental or oropharyngeal organisms that migrate downward into the pleural cavity, is the main cause of VAP. Organisms associated with VAP include *S. pneumoniae* and other streptococci; *Haemophilus influenzae*; *S. aureus*; *Legionella*; *P. aeruginosa*; *Klebsiella*; *Enterobacter*; *Serratia*; *Acinetobacter*; *Stenotrophomonas*; *Burkholderia cepacia*; fungi; and RSV. Frequently these infections are polymicrobial. Although oropharyngeal organisms are primarily seen in early-onset VAP, MDR pathogens are seen more frequently in late-onset VAP, and the associated mortality rate can be as high as 60%.

VAP has been reported as a major complication in patients who are hospitalized with COVID-19. Because of the deterioration of lung function caused from infection by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), many patients, especially older adults, immunocompromised individuals, and others with underlying health issues (e.g., diabetes, high blood pressure, obesity, heart and lung conditions), developed acute respiratory distress syndrome and required mechanical ventilation. COVID-19 patients were far more likely to develop VAP than patients without COVID-19 (28/1000 ventilator days vs. 13/1000 for patients without COVID-19). Preliminary reports indicate that the pathogens seen in these patients are generally the same as those associated with any other VAP, though one study reported a few cases of invasive aspergillosis and herpes virus activation in COVID-19 patients only. It is not yet known how often lung function is permanently damaged by serious infection; it is possible that some COVID-19 survivors could become a new group of immunocompromised patients.

Malignancy

A variety of deficiencies in **humoral-mediated immunity (HMI)**, involving B cells and antibodies, and **cell-mediated**

immunity (CMI), involving T cells, occur in patients with malignancies. Deficiencies can be caused directly by the tumor cells because of the cell type that has become malignant (e.g., leukemias and lymphomas, tumors of the immune system that are more associated with defects in the host immune response compared with tumors of other cell types). Immunosuppressive molecules (cytokines) secreted by the tumor cells can also produce immunosuppression. In addition, cytotoxic drugs administered to patients with cancer to kill the tumor cells contribute substantially to the breakdown of mucosal barriers and decrease CMI in these patients, further suppressing their immune response.

Granulocytopenia, or a reduction in granulocytes to 500 cells/mL or below, is commonly demonstrated in patients with hematologic malignancies and in those receiving chemotherapy. Once the granulocyte count drops below 500/mL to 1000/mL, the risk of infection increases steadily with the degree and duration of immunosuppression. In patients with a neutrophil count below 500/mL, the mortality rate may be as high as 60%. Almost every patient whose neutrophil count is less than 100/mL for 3 weeks or longer will develop an infection. The mortality rate among patients whose neutrophil count is lower than 100/mL during the first week of infection may be as high as 80%.

In addition to the decrease in the number of neutrophils, inadequate neutrophil function, including the inability to migrate to sites of inflammation; impaired phagocytosis; and reduced killing of ingested organisms predisposes patients with chronic leukemia and **Hodgkin disease (HD)** to infections. Most of these infections are caused by bacteria of endogenous origin; that is, GI tract, mucosal, or cutaneous biota. Fungi are also likely to invade the host with granulocytopenia.

Infections in patients with neutropenia

Septicemia often occurs in patients with **neutropenia** (decrease in the number of circulating neutrophils) because neutrophils play an important role in containing infections to a local site. *E. coli*, *K. pneumoniae*, and *P. aeruginosa* account for most infections with gram-negative bacilli. *S. aureus*, coagulase-negative *Staphylococcus*, and *Enterococcus* are the gram-positive organisms most commonly involved in sepsis. Less common pathogens that cause disease in the neutropenic patient include the gram-negative bacteria *Stenotrophomonas*, *Acinetobacter*, *Legionella*, *B. cepacia*, and *Campylobacter* and the gram-positive viridans streptococci. The risk of invasive fungal disease, often caused by *Candida* or *Aspergillus*, increases with time in neutropenia.

Pneumonia, especially when caused by gram-negative bacilli, is a major problem for the patient with neutropenia. Because the patient cannot mount an adequate immune response, pulmonary infection may spread rapidly and extensively. Infections with these organisms are particularly serious because they cause extensive necrosis and have a high fatality rate. Because of the lack of an inflammatory response to infection, patients with neutropenia do not develop the characteristic symptoms of pneumonia, and their infections may remain undiagnosed until after they have become disseminated.

Infections in patients with cancer

In general, cancer patients experience nearly three times the rate of infections as patients without cancer. Factors

responsible for the high incidence of infections among patients with cancer differ depending on the underlying malignancy. For example, tumors that outgrow their blood supply can become necrotic and infected. A GI tumor may ulcerate, providing a focus for invasion by enteric pathogens. Tumors may also obstruct the drainage of the tracheobronchial tree or urinary tract, permitting infection distal to the obstruction to become established. In addition, some cancers can inhibit the immune response, and chemotherapy and radiation treatment can cause neutropenia.

The mortality rate for patients with cancer who have sepsis is approximately 18% to 45%. In various types of cancers, such as lung cancer, the tumor burden is often the leading cause of death. However, infections account for approximately 20% of the deaths. In patients with lung cancer, pneumonia and sepsis are the most common fatal infections. The use of a totally implantable venous access port to deliver medication to patients with cancer has also been shown to slightly increase the risk of infection, such as sepsis. The two most common agents were *Candida* spp. and coagulase-negative staphylococci.

Skin infections are common in patients with cancer for several reasons. These patients often develop decubitus ulcers when they are bedridden for a long time. They also develop catheter-associated infections, cellulitis, and local necrosis involving the extremities, sometimes caused by venipunctures, IV lines, and other procedures.

Patients with hematologic malignancies and those who have undergone surgery for tumors involving the head and spine may experience central nervous system (CNS) infections. Gram-positive organisms are frequently seen in CNS and other infections in patients with cancer. Cancer patients develop meningitis caused by different organisms more often than patients without cancer; for example, more staphylococcal infections occur likely because of surgical manipulations, and there are fewer infections with community-acquired organisms such as *S. pneumoniae*, *H. influenzae*, and *Neisseria meningitidis*.

Fungal agents, such as *Aspergillus* spp. and *Mucor* spp., are associated with brain abscesses that occur in patients with leukemia. Oropharyngeal candidiasis occurs in about 5% of patients with cancer. Superficial GI candidiasis is also found in patients with acute leukemia and lymphoma. Although candidiasis can involve any portion of the GI tract, it is usually found in the esophagus and the stomach. Other areas sometimes affected include the kidneys, liver, spleen, and lungs. *Pneumocystis jirovecii* accounts for as many as 45% of cases of interstitial pneumonia in patients with cancer.

Other types of infections that occur in patients with cancer include those caused by viral and parasitic agents. The most serious viral infections are caused by members of the herpesvirus group. Normally, these viruses infect young patients, resulting in life-long immunity. Such immunity contributes toward maintaining latent infections that occur in immunocompetent individuals. The lack of cellular immunity, especially in immunosuppressed patients with cancer, results in reactivation of the latent virus and the potential for serious disseminated disease.

Herpes zoster, or shingles, occurs on reactivation of latent varicella-zoster virus (VZV). The CDC reports that approximately 1 in 3 individuals will develop herpes zoster in their lifetime. One study, however, reported a 1.9% higher rate of

VZV infection in patients with solid tumors and a 4.8% higher rate in patients with hematologic malignancies compared with the general population. The increased risk of infection is caused primarily by suppression of CMI; disease also correlates with T-cell suppression. Solid tumors do not typically affect immune response; however, systemic chemotherapy does adversely affect the immune response and frequency of zoster infection. Disseminated VZV that spreads to the lungs, liver, pancreas, adrenal glands, and CNS occurs in only 2% of the general population, but up to 35% in cancer patients. The mortality rate from VZV (zoster) infection is about 5% to 15%, and death is usually associated with pneumonitis. Current studies on how varicella vaccination in childhood (available since the 1990s) and zoster vaccination in older adults (available since 2006) affects the incidence and mortality of disseminated VZV in cancer patients will likely change these numbers.

Herpes simplex infections of the lip (cold sores or fever blisters) can result in extensive cellulitis because of superinfection with mixed bacterial and fungal organisms (especially *Candida* spp. and gram-negative bacilli) in patients with cancer. Children with cancer are more susceptible to cytomegalovirus (CMV) infection compared with adults. The most common manifestation is pneumonia that can be unilateral or bilateral and is usually accompanied by a more severe bacterial or fungal infection. Dissemination of CMV affects the lungs, kidneys, lymph nodes, heart, adrenal glands, spleen, pancreas, and bone marrow. Death sometimes occurs as a result of myocarditis, renal failure, or adrenal insufficiency.

Toxoplasma gondii is an obligate intracellular parasite that affects patients with malignancies. Infections may represent reactivation or primary exposure. *T. gondii* causes pneumonia, chorioretinitis, and a mononucleosis-like infection. It is seen most commonly in HD but also occurs in patients with lymphoma and leukemia.

Strongyloides stercoralis, an intestinal roundworm, has been reported in patients with chronic lymphocytic leukemia and lymphoma. Serious manifestations caused by *Strongyloides* infection can occur in patients receiving adrenal corticosteroids or antitumor therapy. Ulceration may result when the rhabditiform larvae penetrate the GI tract. Larval migration to the lungs may cause a pulmonary infiltrate. Interestingly, in many cases, the *Strongyloides* infection is not symptomatic and is not diagnosed until the patient becomes immunosuppressed.

Infections in patients with Hodgkin disease

Historically, HD has been associated with impairment of CMI. Patients with HD are especially susceptible to infections caused by facultative intracellular organisms, such as *Mycobacterium tuberculosis*, *Listeria monocytogenes*, and *Cryptococcus neoformans*, as well as viruses such as VZV. Intracellular organisms are able to multiply within the phagocytic cells and are often resistant to bactericidal and fungicidal agents.

As the number of circulating lymphocytes decreases, patients with HD who are undergoing chemotherapy become more susceptible to infections. Chemotherapy inhibits inflammation, reduces capillary permeability, and decreases cellular exudation. It also interferes with diapedesis of leukocytes, inhibits antibody production, and impairs reticuloendothelial function.

Acquired immunodeficiency syndrome

Acquired immunodeficiency syndrome (AIDS) is caused by HIV, a virus that infects and destroys CD4⁺ T-helper cells. The T-helper cells are critical for stimulating B cells to produce antibodies, cytotoxic T cells to lyse target cells, and monocytes/macrophages to phagocytize and destroy ingested organisms. Because of the integral role of T-helper cells in almost every facet of the immune response, the lack of this cell causes a profound immunosuppression that seriously undermines the body's ability to defend itself from infection and disease.

HIV infection, if not treated, can cause an infected individual to be susceptible to many different infections. HIV-infected individuals are particularly susceptible to infection by opportunistic pathogens and certain cancers. Some of the more common infections include *P. jirovecii* pneumonia, candidiasis of the respiratory tract, extrapulmonary *Mycobacterium tuberculosis* infection, *Mycobacterium avium* complex infection, cryptococcal meningitis, cryptosporidiosis or microsporidiosis with persistent diarrhea, toxoplasmosis encephalitis, CMV infection, herpes simplex virus (HSV) infection, and VZV infection. Kaposi sarcoma, caused by human herpes virus 8 (Kaposi sarcoma-associated herpesvirus); oral hairy leukoplakia, caused by Epstein-Barr virus (EBV); lymphoma of the brain in patients younger than 60 years of age; progressive multifocal leukoencephalopathy; and liver disease and liver tumors (especially if co-infected with hepatitis B or C virus) are also seen in HIV/AIDS patients. HIV/AIDS is discussed more fully in [Chapter 29](#).

Complement deficiency

The **complement** system is a series of proteins that, when activated, increase the activation and function of many different cells involved in the immune response. Complement is particularly important in the opsonization or coating of microorganisms that enhances phagocytosis of the organism by phagocytic cells, such as a neutrophil or monocyte/macrophage. Complement is also directly lytic for microorganisms.

Complement deficiency can be inherited or acquired and typically involves a lack of one particular protein of the system. Development of an autoimmune disease, such as systemic lupus erythematosus, which leads to the increased formation of immune complexes, can result in consumption of complement proteins. Deficiencies of a complement system protein result in increased susceptibility to infections, such as septicemia, pneumonia, or meningitis caused by organisms including *S. pneumoniae*, *H. influenzae*, *N. meningitidis*, members of the Enterobacterales, and staphylococci.

Patients with C3 deficiency are particularly susceptible to sepsis with pyogenic (pus-forming) bacteria, such as *S. aureus* or *Streptococcus pyogenes*. Deficiency in the terminal components of the complement cascade, C56789, results in an inability to lyse gram-negative bacteria, and patients are especially susceptible to developing recurrent bacteremia caused by *N. meningitidis*. Deficiency of the alternative complement pathway leads to serious *S. pneumoniae* infections, including meningitis.

Burns

An American Burn Association fact sheet from 2016 estimates that 486,000 burn injuries necessitating medical treatment, 40,000 hospitalizations, and 3275 deaths as a result of fire and smoke inhalation occur annually in the United States. Most deaths occur at the scene of the fire or shortly thereafter. Infection is a major cause of morbidity and death in those who survive. The risk of infection in a burn patient is directly proportional to the extent of the burn and reflects the combined effect of the impairment of all aspects of the host's defense system. As a result of systemic immunologic impairment, infection in sites other than the burn wound itself remains the most common cause of death among burn patients. Pneumonia is the most common infection seen in burn patients; burn wound infections have decreased in frequency because of vigilant wound care. The balance between host defense capacity and invasiveness of the microorganism in burn patients provides the optimal example of the susceptibility to infection in an immunocompromised patient.

In healthy individuals, bacterial competition (potential pathogens inhibited by the nonpathogenic resident microbiota) plays a significant role in controlling cutaneous colonization of skin. In burn patients, anatomic barriers have been breached, and members of the normal skin microbiota are destroyed or removed by desquamation. The denatured protein of the burn eschar and avascularity of the tissue provide an excellent environment for microbial growth.

The immune defense mechanisms in burn patients, both HMI and CMI, are suppressed. Immunoglobulin concentrations, especially those of immunoglobulin G (IgG), are depressed. Fibronectin levels are also reduced. Fibronectin, a dimeric α -glycoprotein found in plasma and the extracellular matrix of most tissues, is necessary for normal reticuloendothelial cell function and opsonizes *S. aureus*. A decrease in fibronectin levels precedes sepsis. The risk of fungal infections is increased with wound maceration, acidosis, lack of competitive bacterial pressure, and antimicrobial therapy. MRSA; *Enterococcus* (including VRE); *P. aeruginosa*; organisms in the Enterobacterales (increasingly MDR); *Acinetobacter*; *Candida* and other yeasts; *Aspergillus*, *Fusarium*, and *Mucor* spp.; and HSV are major causes of infections in burn patients.

Organ transplantation

The transplantation of solid organs and hematopoietic stem cells from bone marrow, peripheral blood, or umbilical cord blood has increased greatly over the past 30 years. In 2019, there were an estimated 152,863 solid organ transplants performed worldwide. In the United States, 36,000 organ transplantations were performed in 2020, an annual record for the eighth consecutive year. From 1988 to 2018, over 750,000 organs have been transplanted in the United States. To maintain the viability of the graft, immunosuppressive agents are given to organ transplant recipients to prevent immune-mediated destruction or rejection of the graft. Unfortunately, the immunosuppression is not limited to inhibiting the immune cells that recognize the engrafted organ. All cells of the immune system are adversely affected by these drugs, rendering the patient unable to mount a sufficient response to infection.

Organ transplant recipients can develop specific types of infections at certain intervals after transplantation occurs. During the first month after transplantation, postoperative bacterial infections are most common. Significant pathogens include antimicrobial-resistant organisms, including MRSA, VRE, *C. difficile*, and MDR gram-negative rods, such as ESBL-producing and carbapenem-resistant Enterobacterales and *Pseudomonas aeruginosa*. Approximately 1 to 6 months after transplantation, however, infections are caused by slower-growing pathogens, including fungi and viruses. These include *M. tuberculosis*, *L. monocytogenes*, *Nocardia*, *Aspergillus* spp., *Cryptococcus* spp., *Candida* spp., *P. jirovecii*, EBV, CMV, VZV, parvovirus B19, and polyomaviruses BK and JC. Infections with opportunistic organisms, including *Legionella* spp. in the lung and nontuberculous mycobacteria from catheters, occur as well. Bloodstream infections (BSIs) are some of the most common and deadly posttransplant infections, with a mortality rate of approximately 50% when combined with septic shock. The most common gram-negative organism causing BSI in posttransplant patients is *E. coli*, accounting for 36% of BSIs following solid organ transplants. The most common gram-positive organisms causing posttransplant BSI are staphylococci.

Immunosuppressive therapy reactivates latent CMV infection, which is probably the most significant cause of death and morbidity in transplant recipients. Without preventive therapy, 36% to 100% of organ transplant recipients develop CMV infection, and 11% to 72% are symptomatic, many in the first 3 months after transplantation and others in later phases. The direct effects of CMV include tissue infection presenting as pneumonitis, GI disease, hepatitis, and retinitis. Indirect effects linked to CMV after solid organ transplantation include increased risk of secondary infection, presumably because of immunosuppression, increased graft rejection, and accelerated coronary atherosclerosis following heart transplantation.

Infection caused by EBV in transplant recipients has also increased. EBV is recognized as a causative agent of B-cell lymphoma, the pathogenesis of which is related to immunosuppressive therapy. Furthermore, in patients who acquire primary EBV infection after transplantation, EBV-associated lymphoproliferative disease is likely to occur. Primary EBV infection usually develops in children; hence pediatric transplant recipients are at greatest risk. CNS infections caused by *L. monocytogenes*, *C. neoformans*, *T. gondii*, and *Aspergillus* spp. also occur in these patients.

Infections that occur more than 6 months after transplantation are usually associated with community-acquired organisms, such as those causing influenza, secondary bacterial pneumonia, foodborne illnesses (acquired during travel to locations with poor sanitary conditions), and mycotic infections from specific geographic areas that may result in dissemination. Precautions about travel to underdeveloped areas and unfamiliar places are given to transplant recipients to help them avoid unnecessary exposure to community-acquired infections.

Postsplenectomy sepsis

The major risk following splenectomy is overwhelming bacterial infection, or **postsplenectomy sepsis**, resulting from

the body's decreased ability to clear bacteria from the bloodstream and decreased levels of IgM in plasma. Mortality rates can be as high as 60%. Loss of splenic function puts patients at risk of infection from encapsulated organisms. *S. pneumoniae* is the most common, but infections can also occur from *H. influenzae*; *N. meningitidis*; non-encapsulated bacteria including *E. coli*, *Bartonella*, *Capnocytophaga*, and *Pseudomonas*; and the protozoan *Babesia*. The greatest risk of infection is in children, in patients with malignant or immunodeficient disease, and during the first 3 years after splenectomy. Patients should be aware that they are at increased risk of infection and seek medical advice at the onset of fever.

Case check 39.1

The patient in the Case in Point had a splenectomy following a traffic accident that made her particularly susceptible to infections from encapsulated organisms, including *S. pneumoniae*. The health care provider who treated her noted the surgical scar as well as her symptoms and ordered appropriate laboratory tests, including blood and sputum cultures, which helped the health care provider accurately diagnose her infection.

Cystic fibrosis

Cystic fibrosis (CF) is an autosomal recessive disorder caused by a mutation in the CF transmembrane conductance regulator (*CFTR*) gene, which codes for a transmembrane protein that controls the movement of chloride anions across the plasma membrane of cells. Normally, cyclic adenosine monophosphate (cAMP) regulates the transport of chloride across this membrane. The lack of *CFTR* function results in decreased chloride secretion and increased reabsorption of sodium and water by epithelial cells. The lack of water in the mucus causes it to be very thick and sticky. The thickness of the secretions adversely affects the function of the respiratory and GI tracts, sweat glands, and other exocrine glands.

The thick secretions in the lung, in particular, make the patient highly susceptible to chronic infections. According to the Cystic Fibrosis Foundation Patient Registry Annual Data Report of 2014, the most frequently isolated organisms from patients with CF are *S. aureus* (including MRSA) and *P. aeruginosa*. *S. aureus* is more common in children; in adults, *P. aeruginosa* is the dominant isolate, although the percentage of *P. aeruginosa* infections has steadily decreased in the past 15 years. In patients with CF, *P. aeruginosa* is more likely to be resistant to antimicrobial agents and forms a biofilm in a polysaccharide matrix that makes it harder for antimicrobial agents to reach the organism. Research has shown that the production of the polysaccharide and resistance to antimicrobial agents are linked genetically.

Other organisms isolated from the lungs of patients with CF include *H. influenzae*, *B. cepacia*, other nonfermenting gram-negative rods, *Aspergillus fumigatus*, and nontuberculous mycobacteria. Bacteria associated with lower respiratory tract infections in patients with CF often exhibit atypical colony morphology and grow more slowly. For example, *P. aeruginosa* isolates from patients with CF usually produce mucoid colonies from the production of a calcium alginate slime layer. *S. aureus*, commonly recovered from CF patients, can exhibit atypical colonial morphology in culture as well.

Infection with *B. cepacia* is associated with higher mortality and may affect eligibility for lung transplantation because of adverse outcomes after transplantation when the patient is infected by *B. cepacia* before transplantation.

Diabetes

In diabetes, there is insufficient production of insulin by the pancreas (type 1) or insulin resistance of cells (type 2), causing glucose not to enter cells to be used for energy. Because cells cannot take up glucose, body fluids contain increased levels of glucose. High levels of glucose lead to ketoacidosis, in which ketones and organic acids accumulate in blood, lowering the pH (termed *acidemia*). The high level of glucose is immunosuppressive, decreasing neutrophil function and CMI. The immune system suppression can be reversed by decreasing the blood glucose levels and increasing the pH. Infections that are more common in patients with diabetes versus patients without diabetes include the following:

- Pneumonia
- Pyelonephritis
- Soft tissue infections, especially of the extremities, often caused by *S. pyogenes* and *S. aureus*
- Mucocutaneous *Candida* infections
- Gangrenous cholecystitis

Infections that are almost exclusively seen in patients with diabetes include the following:

- Invasive otitis externa caused primarily by *P. aeruginosa*
- Rhinocerebral mucormycosis caused by *Rhizopus*, *Mucor*, and *Absidia* spp.
- Emphysematous pyelonephritis (formation of gas in the kidney)

Aging

Diverse changes in immune function occur with normal aging. Age-induced alterations of the immune system are often more qualitative (e.g., involving lymphocytic function) than quantitative (e.g., involving cell number or immunoglobulin levels). **Immunosenescence**, in which naïve T cells are no longer available to be stimulated by antigen, leads to the decline of the immune response over time. Therefore adults older than 50 years of age are not as likely to mount robust antibody responses to vaccines as well as younger adults. In addition, older adults might be immunosuppressed because they have undiagnosed underlying disease, are taking immunosuppressive medications for a diagnosed disease, or are malnourished. Furthermore, sometimes maintaining personal hygiene standards becomes poorer with aging, and many older adults may be in group housing conditions, both of which increase exposure to infectious microorganisms.

Infections, autoimmune diseases, and malignancies increase among older adult patients because of immunologic decline. Organ function declines with age, and the presence of underlying disease, especially malignancies and diabetes,

which are found more common in older adults, increases the susceptibility of older adults to infection. Infections in older adults usually occur in the respiratory tract (e.g., pneumonia, aspiration pneumonia) or urinary tract (especially catheter-related and enlarged prostate-related infections), skin and soft tissues (infection of pressure ulcers), abdominal cavity, or endocardium. Bacteremia of unknown origin can also occur.

The organisms most often isolated as pathogens in older adults are *S. pneumoniae*, *H. influenzae*, *Moraxella catarrhalis*, and *S. aureus* in cases of pneumonia and enteric gram-negative bacilli, *E. coli* in particular, in other sources. Infections with *Streptococcus agalactiae* (group B *Streptococcus*), *Listeria*, and VZV have increased in incidence and severity. A common and often deadly pathogen in older adults in nursing homes is *C. difficile*. In addition, the incidence of tuberculosis increases with age. Not only are older adults more likely to have serious infections caused by all pathogens when compared with younger individuals, but older adults are more likely to die of those infections. Older adults have a 5 to 10 times higher mortality rate caused by pyelonephritis and a 10-fold higher mortality rate caused by tuberculosis compared with younger patients. The mortality rate of pneumonia is at least three times higher in older adults than in younger patients. This was found to be particularly true during the SARS-CoV-2 pandemic, in which patients older than 50 years of age with COVID-19 disease had more serious symptoms, required ventilation more often, and died in far higher numbers than patients younger than 50 years of age; 95% of deaths have been in people older than 45 years of age.

Pregnancy, the fetus, and the neonate

Infections in pregnant women are of concern, not only to the patient but also to her fetus. Infections can cause preterm birth, spontaneous abortion, birth defects, and developmental disabilities in the offspring and can lead to increased morbidity and death for the woman. Pregnant women are naturally temporarily immunosuppressed so the antigenically different fetus is not rejected, leaving the woman more susceptible to infection and to more serious disease. The immune system in the fetus and neonate is immature, rendering them immunosuppressed as well.

The most common infection in pregnant women is a urinary tract infection, most often caused by *E. coli* and other gram-negative bacilli. Vaginal yeast infections caused by *Candida* spp. are also more common in pregnancy. Pregnant women with bacterial vaginosis are more likely to have premature rupture of the membranes or premature delivery, and the infant may then have a low birth weight because of the premature delivery.

Congenital infections (infections acquired by the fetus in utero) can be caused by the infectious agent crossing the placenta from the bloodstream of the infected woman. These infections can lead to developmental problems and death. Common causes include the following:

- *Toxoplasma gondii*
- Rubella virus
- CMV

- HSV
- VZV
- HIV
- Parvovirus B19
- Hepatitis B virus
- *Treponema pallidum*
- *S. agalactiae*
- *L. monocytogenes*

Other organisms can be transmitted during labor and delivery and in the **perinatal** period, and they are also associated with adverse outcomes (e.g., meningitis, blindness, brain damage) for the infant. Some of the organisms involved cause sexually transmitted diseases and are acquired as the infant moves through the infected birth canal. These agents include the following:

- *Neisseria gonorrhoeae*
- *Chlamydia trachomatis*
- *S. agalactiae*
- *E. coli*
- Human papillomavirus
- CMV
- HSV

POINTS TO REMEMBER

- Immunocompromised patients are susceptible to bacterial, fungal, and viral infections that are usually prevented by a healthy immune system.
- Most infections occurring in immunocompromised patients are caused by opportunistic pathogens of endogenous or exogenous origin.
- Defects in the immune system can be inherited or acquired.
- Successful treatment of infections in the immunocompromised patient depends on recognition of the deficit, early diagnosis, and prompt intervention.

LEARNING ASSESSMENT QUESTIONS

1. What is the most likely sequence of events that led to the febrile condition of the patient in the Case in Point?
2. What is the likely connection between infections and malignancy?
3. What hematologic conditions may predispose patients to various infections?
4. Which organisms are of concern in women who are pregnant?
5. Why are infections and malignancies common among older adults?
6. Which organisms are more likely to cause infections in patients with cystic fibrosis and ventilator-associated pneumonia?
7. Why do patients undergoing chemotherapy and radiation treatment have an increased risk of infections?
8. Infections caused by *Pneumocystis jirovecii* most often affect which of the following?
 - a. Upper respiratory tract
 - b. Lower respiratory tract

- c. GI tract
- d. Urinary tract

9. What is the greatest risk of infections to patients after a splenectomy?
 - a. Gastrointestinal infection
 - b. Skin infection
 - c. Pneumonia
 - d. Septicemia
10. What is the general cause of the increased risk of herpes zoster in patients with tumors?
 - a. Systemic chemotherapy
 - b. Immunosuppression caused by the tumor
 - c. Neutropenia caused by the tumor
 - d. All of the above

Zoonotic diseases

David H. Nielsen and Lindsey E. Nielsen

CHAPTER OUTLINE

Transmission by scratches and bites from domestic or wild animals, 986

Pasteurellosis, 986

Erysipeloid, 986

Capnocytophaga canimorsus infection, 987

Cat scratch disease, 987

Transmission by direct contact or inhalation, 988

Anthrax, 988

Tularemia, 989

Brucellosis, 990

Leptospirosis, 991

Transmission by arthropod vectors, 992

Plague, 992

Lyme borreliosis, 993

Rickettsia infection, 994

Anaplasmataceae infection, 996

Trypanosomiasis, 997

Viral zoonotic diseases, 997

Emerging zoonoses, 998

Bibliography, 999

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Identify the animal hosts and/or vectors associated with the following infections:
 - Anthrax
 - Plague
 - Erysipeloid
 - Leptospirosis
 - Tularemia

- Lyme borreliosis
- Ehrlichiosis and anaplasmosis
- Trypanosomiasis
- Rabies

2. Correlate the pathogen (genus and species) that causes the diseases presented in this chapter.
3. Discuss the epidemiology and the clinical manifestations associated with each disease condition.
 - Anthrax
 - Plague
 - Erysipeloid
 - Leptospirosis
 - Tularemia
 - Lyme borreliosis
 - Cat scratch disease
 - Human granulocytic anaplasmosis
 - Human monocytic ehrlichiosis
 - Trypanosomiasis
 - Rabies
4. Compare the modes of transmission to humans for the following human rickettsial diseases.
 - Rocky Mountain spotted fever
 - Rickettsialpox
 - Murine typhus
 - Louseborne typhus
 - Scrub typhus
5. Describe the characteristics required for a disease to be classified as an emerging zoonotic infection.
6. Justify the need for an accurate patient history to help diagnose zoonotic infections.
7. Analyze the cause of the recent increase in the number of outbreaks attributed to emerging zoonotic infections, the worldwide cost associated with these over the past decade, prevention strategies, and the roadblocks associated with these prevention strategies.

KEY TERMS

Anthrax	Leptospirosis
Brill-Zinsser disease	Morulae
Buboes	Pneumonic plague
Bubonic plague	Rocky Mountain spotted fever (RMSF)
Emerging zoonoses	Tache noire
Erythema migrans (EM)	Tularemia
Eschar	Undulant fever
Human granulocytic anaplasmosis (HGA)	Weil syndrome
Human monocytic ehrlichiosis (HME)	Woolsorter disease
	Zoonoses

Case in point

A 16-year-old female resident of western Colorado experienced pain in the left axilla and arm, with numbness in the arm. The patient developed chills and fever 1 or 2 days later and had multiple episodes of vomiting. She went to the emergency department of a local hospital. The examination found that she had a normal temperature, elevated pulse (100 beats per minute), normal blood pressure, and normal chest x-ray. She reported falling from a trampoline 4 days earlier and was diagnosed with a possible brachial plexus injury related to this incident. The patient was treated with analgesics and given an appointment with a neurologist. Two days later, she was found semi-conscious at home and was taken to the emergency department. On examination, she was found to have a temperature of 39.1° C (102.5° F), reference range 35.6° C (96° F) to 37.5° C (99.5° F); pulse of 170 beats per minute, reference range 60 to 100 beats per minute; blood pressure of 130/70 mm Hg, reference range 90 to 119/60 to 79 mm Hg; altered mental status, neck pain, and generalized soreness. Less than 1 hour after arrival at the hospital, she experienced respiratory arrest and was intubated. Numerous gram-positive diplococci were found in a blood smear, and chest x-rays showed bilateral pulmonary edema. The patient was treated with 2 g ceftriaxone intravenously and transferred to a referral hospital. There she was diagnosed with septicemia, disseminated intravascular coagulation (DIC), acute respiratory distress syndrome, and possible meningitis. Sputum, blood, and cerebrospinal fluid (CSF) were taken for microbiological studies. A Gram stain of CSF revealed white blood cells (WBCs) but no bacteria. She was treated for gram-positive sepsis.

The patient's condition deteriorated rapidly, and she died later that day. Additional cultures of CSF grew unidentified gram-negative rods and *Streptococcus pneumoniae*. In addition, cultures of blood and respiratory aspirates yielded a gram-negative rod initially identified as *Yersinia pseudotuberculosis* by a rapid microidentification method. The blood culture isolate was sent to the state reference laboratory for confirmation and was subsequently identified as *Yersinia pestis*. It was later revealed that an extensive prairie dog die-off had recently occurred adjacent to the patient's residence. Four of five family dogs and one of three family cats had high antibody titers to *Y. pestis* F1 antigen. Investigators concluded that the patient had been infected by direct contact with abscess material from her pet cat while caring for it.

Issues to consider

After reading the patient's case history, consider:

- Zoonotic infections are common; as many as 61% of organisms pathogenic to humans are zoonotic in origin.
- A key piece of information in a patient history is animal exposure.
- Although some zoonoses are asymptomatic or characterized by mild symptoms, others are associated with high mortality.
- A surge in some atypical infections could reflect a larger change has occurred in local animal populations.
- Detection of certain infections in humans, such as West Nile virus infection, anthrax, monkeypox, and avian influenza might indicate an emerging public health threat.

Zoonotic infections are those that can naturally jump from animals to humans. The term *zoonotic* was used first by a German physician in 1855. Infections can be transmitted from animals to humans through various routes, including vectors (mosquitoes, ticks, fleas), skin-to-skin contact, animal bites, inhalation of respiratory droplets, and ingestion of contaminated animal products. Many bacterial zoonotic infections are foodborne or waterborne. According to the Centers for Disease Control and Prevention (CDC), more than 6 of 10 infectious diseases in people are spread from animals. A new viewpoint and appreciation for the zoonoses appeared after a publication by Cleaveland et al. in 2001. In this article, the authors described 1415 microbial species that cause infections in humans. The data included 217 prions and viruses, 538 bacteria and rickettsiae, 307 fungi, 66 protozoa, and 287 helminths. Amazingly, 868 of these pathogenic agents (61%) are zoonotic. To further emphasize the importance of **zoonoses** to human health, of the 175 emerging infections defined, 75% are zoonotic. Clearly, most of the pathogenic agents described in this text are likely to be classified as zoonotic agents.

Some zoonotic infections occur normally in their host animal populations and are able to jump to humans following increased interaction because of animal migration or encroachment of humans into animal habitats. Occasionally, once these infections are introduced into a human population, the zoonotic pathogen can be transmitted from human to human, resulting in a sustained persistence of the agent in the human population. Some of these zoonotic agents include human immunodeficiency virus, influenza virus, Ebola virus, and severe acute respiratory syndrome (SARS)-associated coronavirus. Other zoonotic agents are transmitted from animals to humans, but the resulting disease is generally not contagious from one person to another, so humans essentially represent dead-end hosts. Some zoonotic infections of this type include West Nile virus infection, rabies, ehrlichiosis, bubonic plague, tularemia, brucellosis, leptospirosis, and Lyme borreliosis. Because there are numerous zoonotic agents and infections, this chapter summarizes three major zoonotic disease transmission routes—animal scratches and bites, direct contact or inhalation, and arthropod vectors—and gives bacterial examples for each.

Transmission by scratches and bites from domestic or wild animals

Pasteurellosis

Case study

Parents took their lethargic and irritable 6-month-old daughter to an emergency department. The patient had a low-grade fever and a nonerythematous nodule on the right upper arm, but no sign of rash or lymphadenopathy was present. Two shallow abrasions, possibly scratches from the family's pet cat, were seen near the nodule. The results of the patient examination and laboratory tests were as follows:

- Rectal temperature: 38.9° C (102° F) (reference range 36.1° C [97° F] to 37.5° C [99.5° F])
- Pulse: 200 beats per minute (reference range 100 to 160 beats per minute)
- Respiration: 60 breaths per minute (reference range 30 to 60 breaths per minute)
- WBCs: $2.2 \times 10^9/L$ (reference range 6.0 to $17.5 \times 10^9/L$)
- 57% polymorphonuclear neutrophils (reference range 15% to 45%); 20% band neutrophils (>10% is a critical action value)
- 12% lymphocytes (reference range 47% to 77%); 6% monocytes (reference range 1.4% to 22%)
- Hematocrit: 28% (reference range 30% to 39%)
- CSF: three red blood cells per microliter; 327 WBCs per microliter (reference range <5 per microliter)
- 75% polymorphonuclear neutrophils
- 12% lymphocytes
- Glucose: 48 mg/dL (reference range >60 mg/dL)
- Protein: 79 mg/dL (reference range <40 mg/dL)

Cause

Pasteurellosis is caused by *Pasteurella multocida*, a pleomorphic ovoid to filamentous gram-negative bacillus, about 0.5 to 1.0 μm in size. It can be a primary pathogen or secondary invader. It is pathogenic for a wide range of hosts and occurs in the oral cavities of most dogs and cats (see [Chapter 18](#)).

Clinical manifestations

Pasteurellosis occurs worldwide and encompasses a wide range of endemic diseases of fowl and nonhuman mammals. The most common manifestation of human pasteurellosis is wound and soft tissue infections primarily from the bites or scratches of dogs and cats. Cats are usually involved more often compared with dogs. Although animal bites are the most common source of *P. multocida* infection in humans, animals can also infect preexisting abrasions by licking them. The infected site becomes inflamed within 48 hours, but the presence of pus is rare. Typically, the patient with pasteurellosis is afebrile and does not have inflamed lymph nodes.

Other clinical manifestations include pericarditis, corneal ulcers, upper and lower respiratory tract infections (including epiglottitis, sinusitis, otitis media, and pneumonia), endophthalmitis, and genitourinary tract infections (including pyelonephritis and renal abscess). Rare complications of human infection with *P. multocida* have been reported. These include

sepsis, meningitis, septic arthritis, abscess, peritonitis, and osteomyelitis. The pathogenesis of *P. multocida* infection in humans is not fully understood, but the antiphagocytic capsule and an outer membrane antiphagocytic protein appear to play a key role in dissemination of the pathogen. Some *P. multocida* isolates, including some from humans, produce an exotoxin as well as sialidase, hyaluronidase, surface adhesions, and siderophores. Identification of *P. multocida* infection is based on, the clinical presentation, results of Gram-stained smears; bacterial cultures; biochemical tests; imaging studies, such as computed tomography, magnetic resonance imaging (MRI), and echocardiography; lumbar puncture; arthrocentesis; and paracentesis. Most *Pasteurella* spp. are susceptible to oral antimicrobial agents, including amoxicillin, amoxicillin-clavulanic acid, and fluoroquinolones.

Erysipeloid

Case study

A 67-year-old male patient experienced fever and lower back and bilateral leg pain after falling from a ladder. He went to the emergency department 10 days later and was admitted to the hospital. He was afebrile upon admission, but examination revealed a pruritic erythema of the trunk and extremities. The patient explained that the rash had started as a papule that had spread, showing central clearing. The patient also worked near hog pens. Blood cultures were collected, and routine laboratory tests were done. X-rays showed no bone damage, and the urinalysis was normal.

On hospital day 2, the laboratory reported gram-positive cocci isolated from the blood of the patient. The isolated organism was preliminarily identified as an α -hemolytic *Streptococcus*, but after reexamining the Gram-stained smear and performing biochemical testing, the organism was identified as *Erysipelothrix rhusiopathiae*. The patient was treated with penicillin.

From Gorby, G. L., & Peacock, J. E., Jr. (1988). *Erysipelothrix rhusiopathiae* endocarditis: microbiologic, epidemiologic, and clinical features of an occupational disease. *Reviews of Infectious Diseases*, 10, 317.

Cause

E. rhusiopathiae is the causative agent of the zoonosis erysipelas, seen primarily in pigs (rose disease), and is characterized by fever, skin lesions, arthritis, and sudden death. In humans, *E. rhusiopathiae* causes syndromes referred to as *erysipeloid of Rosenbach*, *erysipelothricosis*, *rose disease*, and *fish handler's disease*. *E. rhusiopathiae* is a thin, non-spore-forming, facultatively anaerobic, gram-positive bacillus, 0.2 to 0.4 $\text{m} \times 0.8$ to 2.5 μm , which can grow singly, in short chains, or in long filaments (see [Chapter 16](#)).

Epidemiology

Often isolated from contaminated water and soil, *E. rhusiopathiae* is important in veterinary medicine. It is found in swine, poultry, dogs, cats, horses, sheep, small mammals, fish, and crustaceans. The organism occurs worldwide. Swine erysipelas is an important economic disease in North America, South America, and Europe. Occupational exposure increases the risk of infection with *E. rhusiopathiae* in farmers, fishermen, butchers, and veterinarians.

Clinical manifestations

The most common clinical manifestation of infection with *E. rhusiopathiae*—erysipeloid—occurs as a result of handling infected animals or animal products. Three clinical manifestations may occur in humans. The first is a localized cutaneous form (also known as *erysipeloid of Rosenbach*) in which the site of infection is usually an abrasion or wound of the hands or fingers (Fig. 40.1). The infection is mild, localized, and self-limiting. An edematous lesion forms 2 to 7 days after infection. Regional lymphadenitis is present in about one third of the patients. Erythema and itching might also be present. The lesion usually heals without treatment within 1 month. The second type is a more diffuse cutaneous form, and the third is a generalized systemic infection with bacteremia. Patients with structural valvular disease, alcoholism, or other predisposing conditions may develop sepsis and endocarditis.

Capnocytophaga canimorsus infection

Case study

A 47-year-old female patient came to the emergency department with weakness, diarrhea, and a facial rash. The patient had a pulse of 80 beats per minute, reference range 60 to 100 beats per minute, and a temperature of 36.5°C (97.7°F), reference range 35.6°C (96°F) to 37.5°C (99.5°F). She had an eschar on the left hand, with no evidence of cellulitis. The facial rash covered her nose and cheeks. There were ecchymoses on her extremities. Her arms and legs were cold to the touch. Lung, cardiac, and central nervous system (CNS) function were normal. The patient was admitted to the intensive care unit.

The patient reported that a dog had bitten her on her left hand 5 days before admission. She had seen a local primary care provider shortly after the bite, and he treated her with corticosteroids for an allergic reaction. The patient received empiric amoxicillin-clavulanic acid and amikacin therapy, followed by ceftazidime and amikacin. The result of aerobic blood culture (one bottle, using Bactec NR-660) was positive, showing a thin, gram-negative bacillus. The blood was subcultured onto brain-heart infusion agar supplemented with 10% horse blood, and small colonies appeared after 48 hours of incubation in carbon dioxide. The laboratory identified the isolate as *Capnocytophaga canimorsus*.

From Hantson, P., et al. (1991). Fatal *Capnocytophaga canimorsus* septicemia in previously healthy women. *Annals of Emergency Medicine*, 20, 93.

Cause

C. canimorsus, previously known as *dysgonic fermenter 2* (CDC group DF-2), is a thin, nonsporing, nonmotile, oxidase- and catalase-positive, gram-negative bacillus, 1 to 3 µm long. The organism grows poorly on laboratory media. This pathogen causes a wide range of clinical manifestations, ranging from a mild, self-limiting localized infection to fulminant septicemia, with involvement of several organs. Infection commonly occurs as a result of handling dogs or cats. The carrier rate for this organism in dogs seems to be low, but inadequate recovery techniques may have influenced this finding.

Clinical manifestations

C. canimorsus is a normal inhabitant of canine and feline oral biota, and infections occur as the result of bites. Dissemination and septicemia occur more often than the self-limiting lesions. About 90% of infections are found in patients with underlying health issues, particularly those who are splenectomized, have

Fig. 40.1 Erysipeloid. An infection of the hands caused by *Erysipelothrix rhusiopathiae* is characterized by blue-red patches on skin. (From Conlon, C. P., & Snyderman, D. R. [2000]. *Mosby's color atlas and text of infectious disease*. London, United Kingdom: Mosby.)

cancer, or have a history of alcohol abuse or intravenous drug use. The most severe infections are seen in splenectomized patients, who develop an endotoxin-mediated Schwartzman-like phenomenon with purpura, septic shock, and DIC. Infection of previously healthy individuals is rare, probably because of the susceptibility of the organism to normal serum killing.

Cat scratch disease

Causes

Cat scratch disease (CSD), also known as *cat scratch fever*, is predominantly caused by the bacterium *Bartonella henselae*. There are currently about 60 species in the genus *Bartonella*. Approximately 50% of those species can cause disease in humans. Some species that infect humans (with vectors and/or animal hosts listed in parentheses) are *B. henselae* (flea, cat), *Bartonella clarridgeiae* (flea, cat), *Bartonella vinsonii* subsp. *vinsonii* (ear mites, voles), *Bartonella vinsonii* subsp. *berkhoffii* (ticks, dogs, coyotes), and *Bartonella vinsonii* subsp. *arupensis* (ticks, mice). *Bartonella bacilliformis* causes the diseases Oroya fever (acute form) and verruga peruana (chronic form). These diseases are not considered zoonoses because humans are the primary reservoir.

CSD was first described in 1889 and was first associated with cats in 1939, when the term *cat scratch disease* was first used. However, the causative agent of the disease was not determined until 1983. Researchers at the Armed Forces Institute of Pathology in Washington, DC, described coccobacilli on patient tissue sections processed using the Warthin-Starry silver stain. After almost a decade of study, the new pathogen was named *Afipia felis*. Serologic data and gene amplification tests were used to determine that most CSD infections were not caused by *A. felis* but rather by *B. henselae* (formerly known as *Rochalimaea henselae*), with some cases also caused by *Bartonella grahamii*. An estimated 12,500 cases of CSD occur annually in the United States, although the disease may be underdiagnosed. Infection is likely transmitted among cats and kittens via cat fleas (*Ctenocephalides felis*). However, human transmission is generally attributed to cat scratches, licks, or bites because almost all patients in whom CSD is diagnosed report exposure to felines, with most of them also recalling a scratch or bite by the feline.

Clinical manifestations

About 1 to 3 weeks after exposure to a cat, symptoms appear. About one half of the patients present with a small skin lesion

(papule) resembling an insect bite. It occurs at the inoculation site, typically on the hand or forearm. The lesion develops into a vesicle and may become a partially healed ulcer. The lesion can heal in a few days to a few weeks. In some cases, unilateral lymphadenitis develops about 3 weeks after exposure. Lymphadenopathy can persist for weeks or months, but often heals spontaneously. Patients may also experience flu-like symptoms, including fever, malaise, and anorexia. The disease in humans is usually mild and self-limiting, lasting anywhere from 6 to 12 weeks in untreated patients. Therefore conservative symptomatic treatment is recommended in patients with mild or moderate CSD.

Case check 40.1

As in the case of many diseases, access to complete patient history, including animal contact and occupational exposure, is the key to accurate diagnosis of CSD. Unfortunately, laboratorians often do not have access to medical records. One strategy for increasing access is by fostering a relationship with the health care provider, particularly the infectious disease staff. Such efforts are encouraged because they provide communication and increase the likelihood that laboratorians will have access to relevant patient information.

Transmission by direct contact or inhalation

Anthrax

Case study

A 57-year-old male patient, employed as an electrician, felt ill and feverish before reporting to the hospital and collapsed at home when he tried to stand. He had been bitten by an insect on the upper left chest the previous day while at work. He was taking no medications and had no travel history. Examination of the patient detected hypotension; a temperature of 38.2° C (101° F), reference range 35.6° C (96° F) to 37.5° C (99.5° F); and a necrotic lesion at the site of the insect bite on the chest, with edema and erythema.

Subsequent laboratory values were as follows:

- Hemoglobin: 17.9 g/dL (reference range 14 to 18 g/dL)
- WBCs: $10.9 \times 10^9/L$ (reference range 4.5 to $11 \times 10^9/L$)
- Platelets: $262 \times 10^9/L$ (reference range 150 to $400 \times 10^9/L$)
- Serum creatinine: 117 $\mu\text{mol/L}$ (reference range 65 to 119 $\mu\text{mol/L}$)
- Serum creatine phosphokinase: 883 IU/L (reference range 20 to 200 IU/L)
- Serum urea: 4.9 mmol/L (reference range 1.8 to 7.1 mmol/L)
- Antistreptolysin O: 240 Todd units (reference range <200 Todd units)

The patient was admitted to the hospital with a diagnosis of streptococcal cellulitis and septicemia and treated with intravenously administered penicillin G and flucloxacillin. The initial diagnosis was proven wrong when the blood culture samples taken at the time of admission became positive for *Bacillus anthracis*. Fortunately, the antimicrobials prescribed were appropriate, and the patient made a full recovery. Misdiagnosis occurred in this case largely because of the rarity of this disease and incomplete patient history. However, it was later determined that the patient had recently worked with untreated imported hides, which, coupled with the necrotic ulcer, would have increased the index of suspicion for anthrax.

From Mallon, E., & McKee, P. H. (1997). Extraordinary case report: cutaneous anthrax. *The American Journal of Dermatopathology*, 19, 79.

Cause

Anthrax, also known as **wool sorter disease** and *malignant pustule*, is caused by *B. anthracis*, a large ($2.5 \times 10 \mu\text{m}$), gram-positive, spore-forming bacillus. This organism occurs naturally in the soil and is a pathogen of herbivores, such as cattle, sheep, and goats. Human infections occur as the result of direct or indirect contact with animals or animal products.

Epidemiology

B. anthracis survives well in soil that is neutral or mildly alkaline. Areas with alternating dry and wet seasons enhance the development of anthrax. Floods tend to concentrate spores, which remain in the grasses after flood waters drain. These spores have been known to survive in fields for as long as 20 years. Animals are then infected by grazing in a contaminated area. Anthrax occurs worldwide, commonly in agricultural regions, such as Central and South America, Africa, and the Middle East. Anthrax is rare in the United States.

Recurrences of anthrax are prevented by containing the spores and eliminating their spread through the environment. Because the anthrax bacteria in tissues do not sporulate until they are exposed to oxygen, infected animal carcasses are usually incinerated whole or are buried in deep pits. Application of lye or quicklime, a practice that has been used to speed up the decay of carcasses, is no longer recommended because calcium ions are now believed to prolong anthrax spore survival. Vaccines are available for humans and for cattle. A cell-free vaccine, prepared from the protective antigen (PA) of *B. anthracis*, is used in individuals working in high-risk occupations. Another vaccine, made with an avirulent, nonencapsulated strain of *B. anthracis*, is available for animals.

Clinical manifestations

Human anthrax manifests in four forms: cutaneous, intestinal, pulmonary, or injectional. The route of transmission determines the incubation period and symptoms.

Cutaneous anthrax

The most common form of anthrax is the cutaneous form (99% of cases), which mimics many other cutaneous infections. It is most common in nonindustrialized countries. The spores enter the host through abraded skin and then germinate. After 48 to 72 hours, a papule is formed; it darkens and ruptures, leaving a painless, craterlike ulcer, which progresses to a necrotic **eschar**. The infection usually remains localized and self-limiting, and the eschar heals without scarring. In about 20% of patients with cutaneous anthrax, the immune system is unable to contain the infection, and *B. anthracis* enters the bloodstream and spreads. With treatment, death is rare.

Gastrointestinal anthrax

The gastrointestinal form, the second most common form of anthrax, is also found more frequently in nonindustrialized nations. It is caused by the ingestion of meat or meat products contaminated with spores. It presents in one of two forms: either as an oral or oropharyngeal form resulting in lesions on the buccal cavity, tongue, or pharyngeal wall; or the intestinal form, producing ulcers anywhere in the gastrointestinal tract. Once the spores are ingested, they germinate, and the organisms gain entry to the intestinal mucosa. Dissemination of the

bacteria can occur via the lymphatics. Clinically, the patient will be febrile and have bloody stools and can lose as much as 12 L of fluid per 24-hour period.

Pulmonary (inhalation) anthrax

The pulmonary form of anthrax is caused by inhaling spores, usually from contaminated animal products. This form of anthrax is more common in industrialized countries. Macrophages ingest the spores and concentrate them in lymph nodes. Eventually, the spores germinate, and sepsis occurs. Symptoms include fever, chills, malaise, and fatigue. This form of infection usually results in death of the patient, which, in the absence of treatment, can occur within 24 hours. The case fatality rate of inhalational anthrax is more than 85%. Administration of antimicrobial therapy and supportive care may reduce the fatality rate, but this treatment appears to be effective only when initiated before the onset of respiratory symptoms.

Injectional anthrax

Injectional anthrax occurs with the injection of drugs of abuse. Even though the route of infection is percutaneous, symptoms differ from those of cutaneous anthrax. Skin near the injection site may be bruised or discolored; however, papules and eschar characteristic of cutaneous anthrax are absent. In injectional anthrax, severe soft tissue infections with edema and necrosis are often present, and this can progress rapidly to septic shock and death. Patients are treated with antimicrobial agents and often with debridement or fasciotomy.

B. anthracis produces three virulence factors: (1) glutamic acid, which inhibits phagocytosis; (2) lethal factor (LF); and (3) edema factor (EF). For LF and EF to become biologically active toxins, they must first combine with the *B. anthracis* protective antigen (PA), which binds to the host cell. PA is also a transport protein, which carries EF and LF into the host cell. EF is an adenylate cyclase that causes characteristic edema. Necrosis occurs as the result of increased capillary permeability and destruction of the phagocytic cells.

Edema can be remarkable and may cause the patient to suffocate by literally swelling the neck shut. Excessive edema of the neck, thorax, and mediastinum signals the beginning of a rapidly fatal course. Several approaches may be considered in the diagnosis of anthrax, depending on the clinical presentation, including examination of the direct Gram-stained smear of tissue, nucleic acid amplification of tissue, chest radiography, computed tomography, blood and tissue cultures, and lumbar puncture. Treatment options include orally administered doxycycline, quinolones, penicillin, raxibacumab, obiltoximab,

and human anthrax immune globulin (Anthraxil) (Table 40.1). Doxycycline and ciprofloxacin may be used prophylactically in individuals who have been exposed to anthrax but have not developed symptoms.

Tularemia

Case study

A 63-year-old male patient noticed swelling and localized pain in the dorsum of his left thumb 5 days after a cat bite. He was treated with orally administered penicillin and cloxacillin for 3 days. He continued to experience pain, general malaise, fever, and vomiting and was admitted to the hospital. The patient was lethargic; his temperature was 38.7° C (102° F), reference range 35.6° C (96° F) to 37.5° C (99.5° F); his chest was clear; and he was hemodynamically stable, with a 3- × 5-cm indurated, erythematous region on the dorsal aspect of the base of his left thumb and hand. Because this was a possible abscess, the health care provider performed an incision and drainage, but no abscess was found. Swabs from the infected region grew coagulase-negative staphylococci.

The patient was treated with intravenously administered penicillin and cloxacillin. Five days after admission, the patient developed shortness of breath and had patchy pneumonic infiltrates of the middle and lower lobes of the right lung. Seven days after admission, lymphangitic streaking on the upper left extremity and tender axillary lymphadenopathy were detected. The patient's therapy was changed to clindamycin and gentamicin. The patient's fever abated, and his respiratory status improved.

A swab from the wound was plated onto sheep blood agar and chocolate agar plates and incubated in 5% carbon dioxide. After 3 days, small, smooth, gray colonies were visible. Gram-negative coccobacilli were identified as *Francisella tularensis* through fatty acid analysis and slide agglutination by using specific antisera. Acute-phase and convalescent-phase serum samples had titers of 1:800 and 1:3200, respectively. The patient's cats were adopted strays that had lived outdoors and had probably fed on wild rodents.

Cause

Tularemia is caused by *F. tularensis*, a strictly aerobic, gram-negative bacillus about 0.2 × 0.2 to 0.7 μm in size. The first isolation of the bacterium was in 1911 during an epizootic outbreak of plaguelike ground squirrel disease. The organism was named *Bacterium tularensis* after Tulare County, California, which was the site of the outbreak. In 1944, researchers defined the role of cottontail rabbits and jackrabbits in the transmission of the disease to humans. Since 1945, the proportion of vectorborne (*Dermacentor andersoni*, *Dermacentor variabilis*, and *Amblyomma americanum*) transmission has increased, whereas transmission from vertebrate reservoirs has decreased. In 1959, the genus name of the organism was changed to *Francisella* in honor of Edward Francis, who first isolated the organism.

Epidemiology

According to the CDC, in the United States, tularemia has been reported in all states except Hawaii. Approximately 240 cases of tularemia are reported annually. *F. tularensis* is found predominantly in the Northern Hemisphere. The two biovars *F. tularensis* biovar *tularensis* (type A) and *F. tularensis* biovar *palaeartica* (type B) occur in different parts of the world. In North America, the predominant biovar is type A, the strain that is more virulent in humans. Humans are usually infected

Table 40.1 Anthrax treatment and management

Clinical presentation	Treatment
Cutaneous anthrax	Oral doxycycline or quinolones
Nonbioterrorist anthrax, inhalational anthrax, anthrax meningitis	Penicillin
Bioterrorist anthrax	Doxycycline or quinolones
Inhalational anthrax or for prevention when alternative therapies are not available	Raxibacumab, Anthim (obiltoximab)
Inhalational anthrax in adults and children	Human anthrax immune globulin (Anthraxil) in combination with antimicrobial therapy

with this strain by rabbits or ticks, although more than 100 species of vertebrate and invertebrate natural reservoirs can transmit the infection. Type B occurs throughout the Northern Hemisphere but is more often recovered in Europe and Asia. It is less virulent than type A and is usually transmitted by rodents and mosquitoes. Types A and B differ from each other biochemically and genetically but not serologically.

Clinical manifestations

Tularemia is an acute, febrile, granulomatous disease characterized by rapid onset and flulike symptoms. The most common presentations are ulceroglandular (ulcers and lymphadenopathy), oropharyngeal (pharyngeal ulcer and lymphadenopathy), oculoglandular (conjunctival ulcer and lymphadenopathy), glandular (lymphadenopathy without ulcer), pleuropulmonary (no ulcer, possible lymphadenopathy), and typhoidal (no ulcers or lymphadenopathy). The ulceroglandular, oculoglandular, and glandular types usually occur as the result of direct contact with infected vertebrate or invertebrate reservoirs. Typhoidal and oropharyngeal cases of tularemia usually occur after eating contaminated food.

Pneumonic tularemia may result from exposure to aerosols. The symptoms associated with tularemia include fever, chills, headache, and myalgia. Typhoidal tularemia, especially when complicated by pneumonia, has a high fatality rate. In the United States, most cases of tularemia are of the ulceroglandular type. These infections are usually caused by direct contact with contaminated game or by insect bites. The incubation period of tularemia is typically 3 to 5 days. A papule, which forms at the site of infection, eventually ulcerates. Patients usually have only one lesion, although multiple lesions can occur. Because the disease is rare and

there are no characteristic symptoms, patients are often initially misdiagnosed. The actual site of the lesion is indicative of the transmission; lesions of the hands or arms often indicate infection by direct contact with infected mammals, whereas lesions on the head or back are suggestive of insect vector transmission. Streptomycin is the drug of choice to treat tularemia. Gentamicin and amikacin are acceptable alternatives.

Brucellosis

Causes and epidemiology

Brucellosis is referred to by many other terms, including *Mediterranean fever*, *Malta fever*, *Gibraltar fever*, *Bang disease*, *Neapolitan fever*, *Cyprus fever*, and **undulant fever**. The genus name comes from Sir David Bruce, who, in 1887, was first to describe these agents as the cause of undulant fever. In the United States, fewer than 100 cases of brucellosis are reported annually. Four species, which originate from animal reservoirs, are pathogenic to humans, in descending order:

- *Brucella melitensis* (goats)
- *Brucella suis* (swine)
- *Brucella abortus* (cattle)
- *Brucella canis* (canines)

Other species not known to cause human disease are *Brucella neotomae* (desert wood rat) and *Brucella ovis* (sheep). In animal hosts, brucellae can induce spontaneous abortion secondary to bacteremia. While the urine and milk of infected animals contain infective organisms, most animal infections are asymptomatic. *B. melitensis*, the most common agent of human brucellosis, occurs in many areas of the world, including Mexico, Central and South America, southeastern Europe, countries bordering the Mediterranean, Africa, southern Russia, India, Iran, and central Saudi Arabia.

Clinical manifestations

In the United States, brucellae infect humans primarily through eating undercooked meat or consuming unpasteurized (raw) dairy products. Contact with infected animals and animal products, including inhalation, can also lead to infection. Veterinarians, meat packers, shepherds, and abattoir workers have the highest risk of infection. The organism can enter the body through abraded skin, mucous membranes (e.g., gastrointestinal tract), or the conjunctivae. In experiments, *B. abortus* has even penetrated intact skin.

After an incubation period of 1 to 3 weeks, brucellae are disseminated hematogenously, where circulating monocytes ingest them. Brucellae are facultative intracellular parasites. Monocytes transport brucellae to lymph nodes. From there, the bacteria spread to the spleen and the liver. *B. abortus* usually causes granuloma formation, whereas *B. melitensis* usually causes formation of microabscesses. *B. melitensis* is also able to inhibit phagosome-lysosome fusion in phagocytic cells, allowing intracellular bacterial replication. Normal human serum is bactericidal to *B. abortus*, but not to *B. melitensis*, accounting for the relative differences in their pathogenicity. The symptoms of acute brucellosis are chills, fever, sweating, weakness, myalgia, and fatigue.

Case study

A 25-year-old male patient complaining of headache, malaise, arthralgia, and a 6-kg weight loss was admitted to the hospital. His symptoms started 3 months ago after his return from a trip to Syria. He reported having eaten fresh goat cheese. On admission, he was in moderate distress and had the following laboratory results:

- WBCs: $5.3 \times 10^9/L$ (reference range 4.5 to $11 \times 10^9/L$)
- C-reactive protein (CRP): 10.7 mg/dL (reference range $<1.0 \text{ mg/dL}$)
- Malaria smear: negative
- Serology for *Salmonella* spp.: negative
- Blood culture: positive for *Brucella abortus*
- Serology for *B. abortus*: positive, titer 1 : 10,000

The patient was treated daily with oral doxycycline, 400 mg, and rifampin, 600 mg. The patient's condition improved, he became afebrile, and his CRP level returned to normal after a few days. The patient's girlfriend developed the same symptoms 2 months later and was admitted to the hospital. Blood culture results were positive for *B. abortus*. She was successfully treated and recovered without complications.

The authors believed this to be the first case of possible sexual transmission of *B. abortus* in humans. The female had no travel history or other risk factors. The couple had unprotected sexual intercourse, and sexual transmission was considered to be the most likely route of infection.

From Thalhammer F., et al. (1998). Unusual route of transmission for *Brucella abortus*. *Clinical Infectious Diseases*, 26, 763.

Leptospirosis

Case study

A 48-year-old male patient, employed as a river dredger, presented with headache, fever, dark urine, arthralgia, diarrhea, breathlessness, and confusion, which had become worse over the past 4 days. The patient had hypoxia, and chest x-rays showed rapid deterioration, with shadowing in all regions of the lungs. He was treated with doxycycline and erythromycin. His condition continued to deteriorate, and he was given mechanical respiratory support. Methylprednisolone was prescribed in addition to the antimicrobials. Chest x-rays showed continued deterioration for a period of 7 days before showing gradual clearance. Renal function also returned to normal. He was discharged after 21 days. It was determined that the patient had culture-positive leptospirosis, with severe pulmonary hemorrhage. The date of the positive culture result was not reported.

Reviews of the Tropical Public Health Unit records showed 149 cases of leptospirosis. Of the 24 patients hospitalized, 5 had life-threatening pulmonary hemorrhage. Although not frequently reported, this complication is worth noting because of its serious consequences. In the authors' experience with the five cases, all patients gave nonspecific histories of malaise, myalgia, and fever. Renal impairment and jaundice, considered the hallmarks of leptospirosis, were absent in two of the five patients.

From Simpson F. G., et al. (1998). Leptospirosis associated with severe pulmonary haemorrhage in Far North Queensland. *The Medical Journal of Australia*, 169, 151.

Cause

Leptospire are spirochetes, about 6 to $20 \times 0.1 \mu\text{m}$ in size (Fig. 40.2). They are motile and have two subterminal flagella. The cells have characteristic hooks on the ends. The genus *Leptospira* contains a large group of serologically diverse organisms. Nearly 70 species are in the genus. As many as 250 serovars are organized into 23 serogroups.

Epidemiology

Until recently, **leptospirosis** was not considered a widely prevalent infection. Current thought suggests that this

Fig. 40.2 Photomicrograph of *Leptospira* taken from a liver preparation in a patient with fatal leptospirosis (silver stain, $\times 1000$). (Courtesy Dr. Martin Hicklin, Centers for Disease Control and Prevention, Atlanta, GA.)

infection is one of the most common zoonoses, primarily as a result of exposure during recreational activities. It is most often reported in the United States from the southeastern, Gulf coast, and Pacific coast states and Hawaii and the U.S. territory Puerto Rico. About 100 to 150 cases of leptospirosis are identified annually, with the highest annual occurrence rate reported in Puerto Rico followed by Hawaii. Recreational activities that involve contact with water or moist soil are usually associated with transmission. In Hawaii, some homes have rainwater catchment systems, and these have also been reported as a risk factor. In as many as 5% to 10% of cases, leptospirosis is fatal.

Rodents and domestic animals are the primary reservoirs for the organism, although other animals, including cows, horses, mongooses, and frogs, can also harbor leptospires. Humans may be directly infected through contact with animal urine or indirectly by contact with soil or water that is contaminated by urine from infected animals. The usual portal of entry is via cuts or abrasions in the skin or along mucous membranes. The patient in the Case in Point worked as a river dredger and doubtless had frequent repeated contacts with untreated water. Infected humans can shed leptospires in urine for up to 11 months, infected cows can shed them for 3.5 months, infected dogs can shed them for 4 years, and infected rodents can shed them possibly during their entire lifetime.

Veterinarians, abattoir workers, fish and poultry processors, and dairy workers are at risk for leptospirosis. Agricultural workers and soldiers are also at risk because of contact with soil and mud. Leptospirosis is endemic in most areas of the world, although the incidence of disease might be underreported because of the difficulties associated with diagnosing infections. The infection is more prevalent in areas with warm climates, especially in late autumn and early winter.

Clinical manifestations

Leptospiral infections can range from subclinical to lethal. The organisms enter the host through mucous membranes or abraded skin. The incubation period ranges from 5 to 14 days. Most cases of leptospirosis are subclinical or mild. Anicteric leptospirosis is usually a biphasic disease. The first phase, known as the *leptospiremic* or *febrile phase*, typically lasts about 1 week. This phase is characterized by sudden temperature spikes, severe headaches, nausea, vomiting, and muscle aches. Patients often experience confusion secondary to dehydration. Additionally, most patients develop vivid pink eyes. During this period, leptospires can be recovered from the patient's blood and CSF.

The second phase of anicteric leptospirosis is referred to as the *convalescent* or *immune phase*. During this period, leptospires disappear from the circulatory system and CSF. This change occurs after the appearance of specific immunoglobulin M antibodies. Symptoms may subside for a few days, but a limited febrile episode may follow. Patients can also develop aseptic meningitis and severe headaches. During this stage of infection, the urine contains leptospires, but the blood of the patient does not. The length of this stage depends on the serotype of the infecting leptospire but is generally between 4 and 30 days.

Leptospira interrogans serovar *icterohaemorrhagiae* can cause icteric leptospirosis, also known as **Weil syndrome**.

This form of leptospirosis is more life-threatening than the anicteric form and is seen in 5% to 10% of all patients with leptospirosis. Weil syndrome starts in the same way as anicteric leptospirosis. Around the third day of the illness, however, the patient develops hemolysis, jaundice, and renal failure. These symptoms occur as the leptospires multiply in the liver and kidney. The mortality rate of Weil syndrome ranges from 5% to 15%. In fatal cases, renal failure is the usual cause of death. In nonfatal cases, as antibodies are produced, leptospires clear from the patient's kidneys, brain, and eyes. The treatment of choice for mild leptospirosis is doxycycline, ampicillin, or amoxicillin, and severe leptospirosis is treated with intravenously administered penicillin G.

Case check 40.2

Although many diseases that fall into the category of zoonotic may have pathognomonic symptoms, the patient's history, including animal contact and occupational exposure, is key to a timely and accurate diagnosis.

Transmission by arthropod vectors

Plague

Cause

Plague is caused by the gram-negative bacillus *Y. pestis*. This genus is named for Alexandre Yersin, a French microbiologist who isolated the plague bacillus during an epidemic in Hong Kong in 1894. Historically, three pandemics have occurred; Black Death, the notorious second pandemic, caused 25 million deaths ($\approx 30\%$ of the European population). Rats are the natural host for the fleas that transmit the disease from one host to another by means of a bite, and humans are accidental hosts. Fleas (*Xenopsylla cheopis*) are the vectors (Fig. 40.3) that normally infest brown (*Rattus norvegicus*) and black (*Rattus rattus*) rats. In addition to rats, plague is also common in species included in the family Sciuridae such as prairie dogs (*Cynomys* spp.) and squirrels (*Sciurus* spp.).

The United States averages 7 human plague cases annually, with most cases occurring in the Southwest. The organism persists in this region through the sylvatic cycle, being passed among fleas and their natural hosts. *Y. pestis* can survive for months in animal burrows, and uninfected hosts can become infected from this reservoir. The risk of humans becoming infected with *Y. pestis* increases when human dwellings encroach on infested host habitat, when natural hosts are eradicated and fleas seek new hosts, or when living conditions are favorable to infested host cohabitation in rural or urban areas. Transmission to humans can also occur via domestic cats that hunt rodents.

Life cycle

Fleas develop yersiniosis when they take a blood meal from an infected animal host. Yersiniae multiply in the gut of the

flea, eventually reaching such a high concentration that they block the flea's gut. This blockage impairs the flea's ability to feed, and infection begins when the fleas regurgitate the plague bacilli into the bite wound while feeding. In response to a lack of nutrition, fleas infest a wider range of hosts including humans and will bite more often.

Clinical manifestations

Plague has two major manifestations: bubonic and pneumonic forms. **Bubonic plague** is an acute, febrile disease with an incubation period of 1 to 7 days. The disease is usually characterized by a lesion in a regional lymph node that drains the infected area. The resulting painful **buboes** usually occur in the groin, axillae, or subauricular area. In the Case in Point, the patient complained of a painful axilla and numbness in her arm. This may have been the beginning of bubo formation. Within 3 to 6 days after the onset of infection, the patient developed signs of septic shock. If untreated, the organism can be disseminated hematogenously, leading to septicemia. However, septicemic plague may occur without the bubonic form. The mortality rate of septicemic plague is almost 100%, with death occurring within 1 to 3 days.

Septicemic plague may lead to secondary pneumonia, referred to as **pneumonic plague**. Pneumonic plague is almost always the result of hematogenously spread bubonic or septicemic plague. There are two forms of pneumonic plague: primary and secondary. Primary pneumonic plague occurs when the patient acquires the organism via infectious airborne droplets; secondary pneumonic plague results from the plague bacillus entering the lungs of the patient who has either bubonic or septicemic plague. Pneumonic plague presents an increased risk of person-to-person transmission because respiratory droplets produced during coughing are extremely infectious. In the absence of respiratory precautions, this form may lead to localized or devastating outbreaks.

Lyme borreliosis

Case study

A 28-year-old female patient came to the emergency department with shaking chills and perspiration. She explained that before the fever she had swollen and painful ankles, knees, wrists, and elbows. Her temperature was 38° C (100.4° F), reference range 35.6° C (96° F) to 37.5° C (99.5° F), and synovitis was noted in the wrists, elbows, knees, and ankles. She had no rash or lymphadenopathy. She reported a family history of osteoarthritis and rheumatoid arthritis. The patient lived in a rural area and showed evidence of multiple insect bites, although she could not remember any recent tick bites. The patient was treated with naproxen and doxycycline for polyarthritis, systemic lupus erythematosus, and late-stage Lyme borreliosis.

Cause

Lyme borreliosis, caused by the spirochete *Borrelia burgdorferi*, is an arthropod-borne disease for which humans are accidental hosts (see [Chapter 23](#)). The disease is primarily transmitted by ticks, including *Ixodes affinis*, *I. dammini*, *I. scapularis* (the deer or black-legged tick), *I. pacificus* (western black-legged tick), and *I. ricinus* (the European sheep tick). *B. burgdorferi* organisms are gram-negative spirochetes about 0.18 to 0.25 $\mu\text{m} \times 4$ to 30 μm in size ([Fig. 40.4](#)).

Epidemiology

Lyme borreliosis, or Lyme disease, is the most common vector-borne disease in the United States, with approximately 30,000 cases reported annually. Lyme borreliosis exists throughout the world, with about 65,000 cases reported each year in Europe. The disease, which would eventually be named *Lyme borreliosis*, was probably first noted in Sweden in 1908. At that time, erythema chronicum migrans (recently simplified to **erythema migrans [EM]**) was described as a rash with expanding margins. In EM, red circles ring a white, hard center of the rash, resulting in a “bull’s eye” appearance ([Fig. 40.5](#)).

The next several decades saw more cases of EM in Europe. The first report of a similar phenomenon in the United States was in 1970. In 1975, an outbreak of juvenile rheumatoid

arthritis occurred in Lyme and Old Lyme, Connecticut. The clustered outbreak of juvenile rheumatoid arthritis appeared suspicious, and thanks to some family members who thought that an infectious agent might be involved, an investigation was initiated by health officials. It was Willy Burgdorfer’s accidental discovery of spirochetes in the blood of ticks recovered from the Old Lyme area that ultimately led to the description of Lyme disease. In 1984, the name *Borrelia burgdorferi* was proposed for these organisms. Lyme disease has a bimodal age distribution, with the first peak at 5 to 14 years of age and the second at 45 to 54 years of age.

Life cycle

Ixodes ticks typically have a 2-year life cycle, requiring blood meals to pass from the larval stage to the nymph stage and from the nymph stage to the adult stage. Nymphs and larvae feed primarily on the white-footed mouse, whereas adult ticks typically infest the white-tailed deer. This horizontal transmission ensures maintenance of the pathogen in the wild. Infected nymphs transmit the organism directly into the tissue of hosts (including humans) by regurgitating during feeding. Nymphs transmit the disease primarily in spring and summer. Their very small size poses the greatest threat because they are very hard to see.

Clinical manifestations

There are three stages associated with Lyme borreliosis: early localized, early disseminated, and late persistent. However, staging can be difficult because presentation varies by patient, and some may not exhibit all stages described in the typical illness. In about two thirds of infected patients, the early localized stage is characterized by a red papule that appears at the site of the tick bite within the first 30 days of infection. The papule, referred to as an *erythema migrans*, is the characteristic rash of Lyme borreliosis. It can expand to form erythematous concentric rings, with central clearing. Early

Fig. 40.4 Spirochetes of *Borrelia burgdorferi* (Dieterle silver stain preparation, $\times 1000$). (Courtesy Centers for Disease Control and Prevention, Atlanta, GA.)

Fig. 40.5 Patient with multiple erythema migrans lesions. (From Berger, B. W. [1989]. *Dermatologic manifestations of Lyme disease*, *Reviews of Infectious Diseases* 11, S1475.)

diagnosis and treatment can be very complicated in patients who do not exhibit EM because they may not even remember having been bitten by a tick.

The other symptoms associated with the early localized stage include nonspecific flulike symptoms, including malaise, lymphadenopathy, low-grade fever, headache, and neck stiffness. The second or early disseminated stage typically appears weeks to months after infection. During this stage, the most clinically significant symptoms are neurologic, such as Bell palsy, neurologic deficits, and meningitis. Other symptoms that may appear include oligoarthritis and carditis. Late persistent Lyme borreliosis is characterized by relapsing arthritis that can occur months to years after the initial symptoms. The joints most commonly affected are the knees, shoulders, and elbows. Untreated patients may have decreasingly severe attacks over time, until the symptoms eventually disappear.

Because the concentration of bacteria in the host remains low through the course of the disease, it is possible that many of the effects seen in Lyme borreliosis result from the host's immune response, including attraction of macrophages to synovial fluid and production of interleukin-1 by host monocytes. Lyme spirochetes are rarely isolated from the blood or other body fluids of infected patients. Apparently, the organism prefers solid tissue rather than fluid. The spirochete has a nonspecific adhesion that allows it to attach to the endothelial cells of blood vessels. This ability may enhance the migration of the organism from the bloodstream into the basement membrane, resulting in vascular damage that can lead to carditis, arthritis, and CNS disease. Treatment and management of Lyme borreliosis are guided by the patient's clinical presentation, stage of the disease, and the presence of any allergies.

Rickettsia infection

General characteristics

Rickettsia spp. are nonmotile, gram-negative bacilli, about 0.8 to 2.0 $\mu\text{m} \times 0.3$ to 0.5 μm in size; they are arthropod-borne,

obligate intracellular bacteria that can grow only in the cytoplasm of host cells. They spend at least part of their life cycle in an arthropod. Arthropod hosts generally serve as both reservoirs (transovarial transmission) and vectors (transmission between mammalian hosts) for members of the genus *Rickettsia*. Members of the genus have been grown in cell lines and embryonated eggs. However, because of their infectious nature, any attempt to cultivate them in clinical laboratories without proper equipment and training is not recommended. The rickettsiae are divided into two main groups according to the types of clinical infections they produce. The spotted fever group contains about a dozen species including *R. rickettsii*, *R. parkeri*, *R. conorii*, and *R. africae*; the typhus group consists of *R. prowazekii* and *R. typhi*. A third transitional group contains the human pathogens *R. akari*, *R. australis*, and *R. felis*.

Spotted fever group

Rocky Mountain spotted fever (RMSF), caused by *R. rickettsii*, is the most severe of the rickettsial infections and the most common in the United States. Humans acquire the infection by tick bites. *Dermacentor variabilis* in the southeastern United States and *D. andersoni* in the western part of the country are the vectors of *R. rickettsii*. Rodents and ticks serve as reservoirs. Incidence and case fatality rates of RMSF in the United States have been recorded since the 1920s (Fig. 40.6). Because of the difficulty and inability to differentiate between spotted fever group *Rickettsia* species using commonly available serologic tests, cases of RMSF have been reported under the category called spotted fever rickettsiosis (SFR). The category includes cases of RMSF, *Rickettsia parkeri* rickettsiosis, Pacific Coast tick fever (*Rickettsia* species 364D), and rickettsialpox (*R. akari*). According to the CDC, the number of SFR cases has increased in the past two decades, reaching a peak of 6248 in 2017. However, cases reported in 2018 and 2019 were slightly lower.

The bacteria preferentially infect the endothelial cells, where they replicate primarily in the cytoplasm of the host cell. Rickettsiae spread hematogenously throughout the host and

Fig. 40.6 Incidence and case fatality rate of Rocky Mountain spotted fever in the United States, 1920 to 2020. (Courtesy Centers for Disease Control and Prevention Atlanta, GA.)

induce vasculitis in internal organs, including the brain, heart, lungs, and kidneys. After an incubation period of approximately 7 days, the patient presents with flulike symptoms that include fever, headache, myalgia, nausea, vomiting, and rash. The rash begins as erythematous patches on the ankles and wrists during the first week of symptoms and then extends to the palms of the hands and soles of the feet. However, it normally does not affect the face. The maculopapular patches eventually consolidate into larger areas of ecchymoses. Other symptoms include hypotension and DIC. With rapid diagnosis and appropriate therapy, the mortality rate is 3% to 6%. The mortality rate without treatment can be 20% or higher.

Boutonneuse fever (BF), also known as *Mediterranean spotted fever*, is caused by *R. conorii* and occurs primarily in France, Spain, and Italy. *R. conorii* also causes Kenya tick typhus, South African tick fever, and Indian tick typhus. The brown dog tick, *Rhipicephalus sanguineus*, is the primary vector of *R. conorii* worldwide. Like the agent for RMSF, reservoirs include ticks and dogs.

BF clinically resembles RMSF because it causes a rash that commonly involves the palms of the hands and the soles of the feet. Unlike RMSF, the rash may also involve the face, and infection may be marked by a pathognomonic symptom known as **tache noire**, which is a small, 2- to 5-mm, black-centered ulcer that appears at the bite site. Other symptoms associated with BF include lymphadenopathy. BF is typically considered much milder than RMSF because the case fatality rate, even without treatment, is estimated at 3%, but severe complications with neurologic involvement occur in about 6% to 10% of patients.

Rickettsialpox, caused by *R. akari*, occurs in Korea and Ukraine as well as in the eastern United States. The disease was first reported in the United States in an apartment in the borough of Queens, New York, in 1946. Outbreaks have occurred in several large cities, including New York, Cleveland, and Philadelphia. The reservoir is the common house mouse, and the vector is the mouse mite. Infections occur in crowded urban areas where there are rodents and their mites. Rickettsialpox is similar to RMSF but milder. After an incubation period of about 10 days, a papule forms at the site of inoculation. The papule progresses to a pustule and then to an indurated eschar. Additional symptoms include headache, nausea, and chills. Unlike RMSF, the rash of rickettsialpox appears on the face, trunk, and extremities and does not involve the palms of the hands or soles of the feet. Rickettsialpox symptoms resolve without medical attention.

Typhus group

Murine typhus

Murine (endemic) typhus is caused by *Rickettsia typhi*. The arthropod vector is the oriental rat flea, and the rat is the reservoir. The cat flea can also serve as a reservoir. Because this flea infests a large number of domestic animals, it may be an important factor in the persistence of infection in urban areas. The rickettsiae also survive in nature, to a lesser extent, by transovarial transmission.

In the 1940s, approximately 5000 cases of endemic typhus were reported annually in the United States. Although it is no longer a reportable disease in the United States, fewer than 100 cases are reported annually. The disease essentially occurs only in southern Texas and southern California.

Worldwide, it continues to be a problem in areas where rats and their fleas are present in urban settings. As with RMSF, the clinical course of murine typhus includes fever, headache, and rash. Unlike RMSF, however, rash appears in only about 50% of patients with murine typhus. When the rash is present, it is usually on the trunk and extremities. Patients often have an eschar at the site of inoculation. Complications are rare, and recovery usually occurs without incident.

Louseborne typhus

Louseborne (epidemic) typhus is caused by *R. prowazekii*. Vectors of this disease include the human louse, squirrel flea, and squirrel louse. The reservoirs are primarily humans and flying squirrels located in the eastern United States. Unlike vectors of other rickettsiae, the louse often dies as a result of its rickettsial infection.

Louseborne typhus is still commonly found in areas of Africa and Central and South America, in areas where overcrowding and poor sanitation promote the presence of body lice. As demonstrated during World War II, epidemic typhus can occur even in developed countries when sanitation is disrupted. More than 20,000 cases of louseborne typhus were documented during the 1980s, with the vast majority originating in Africa.

Lice are infected with *R. prowazekii* when feeding on infected humans. The organisms invade the cells lining the gut of the louse and spill into the lumen of the gut when infected cells lyse. When the louse feeds on another human, it defecates, and the infected feces are scratched into the skin. Disease progression resembles that of RMSF, including a rash involving the palms of the hands and soles of the feet. Unlike RMSF, the face may also be affected by the rash.

Mortality rates in treated patients are very low; however, the mortality rates for untreated patients can approach 40%. **Brill-Zinsser disease**, or recrudescent typhus, is a reactivation of louseborne typhus. The bacteria can lie dormant in the lymph tissue of the human host for several years after the primary infection. Recrudescent typhus is milder than louseborne typhus, and death is rare. Patients with latent infections are an important reservoir for the organism.

Scrub typhus

Orientia tsutsugamushi (scrub typhus) is phylogenetically distinct from the rickettsiae. Many species of chigger mites in the family Trombiculidae serve as vectors for scrub typhus. Several mammalian hosts serve as reservoirs, with rodents being the principal reservoirs in Asia. Scrub typhus is common in southeast and central Asia and in the oriental region of the world. Scrub typhus is associated with rural areas where human risk is elevated when conducting nonmechanized agricultural practices of field sanitation or harvest. Annually nearly 1 million new cases are reported worldwide.

Chigger larvae are the only life stage that can acquire and transmit scrub typhus. *O. tsutsugamushi* is maintained in the chigger population through transstadial and transovarial transmission. Infection among the chigger population also occurs when uninfected chiggers cofeed on a host being parasitized by infected chiggers. Chigger larvae will infest rodent nests or other mammalian hosts. Unlike other rickettsia vectors, chiggers do not take a bloodmeal; they use their saliva to dissolve tissue, creating a stylostome. The stylostome, similar to a drinking straw, is the reason that bites have a pustule center.

O. tsutsugamushi is maintained in the salivary glands of the chigger and is transmitted to the host during stylostome development and subsequent feeding. Once in the mammalian host, *O. tsutsugamushi* begins to attack myelocytes and eventually endothelial cells near the stylostome. The pathogen survives the human immune response by interacting with host cells, causing them to create a clathrin-coated vesicle that transports *O. tsutsugamushi* to the cytoplasm, where it can begin attacking new cells and multiplying.

Humans are considered an incidental host but can serve as a reservoir to uninfected chigger populations. The chigger feeds on the host for 2 to 4 days and detaches. The stylostome leaves a pustule that is often itchy. Scrub typhus has symptoms similar to other rickettsial infections, which include fever, chills, body aches, enlarged lymph nodes, rash, and an eschar at the sight of the bite. If left untreated, patients can develop organ failure and bleeding, which can be fatal.

Anaplasmataceae infection

Case study

A 65-year-old male patient was experiencing fever, headache, myalgia, and anorexia for 5 days. When he went to his personal health care provider, his temperature was 38.3°C (101°F), reference range 35.6°C (96°F) to 37.5°C (99.5°F); his blood pressure was 128/60 mm Hg, reference range 90 to 119/60 to 79 mm Hg; and he was dehydrated. There was no sign of rash or lymphadenopathy. Serial blood culture results and routine serology tests were negative. The patient received doxycycline intravenously for 3 days. He then received doxycycline orally. His fever resolved after 6 hours of therapy. The following are the laboratory test results:

- WBCs: $2.5 \times 10^9/\text{L}$ (reference range 4.5 to $11 \times 10^9/\text{L}$)
- Platelets: $57,000/\mu\text{L}$ (reference range 150 to 400)
- Hematocrit: 41.1% (reference range 40% to 54%)
- Hemoglobin: 11.6 g/dL (reference range 14 to 18 g/dL)
- Aspartate aminotransferase: 167 U/L (reference range 6 to 34 U/L)
- Creatine phosphokinase: 403 U/L (reference range 20 to 200 IU/L)
- Alkaline phosphatase: 173 IU/L (reference range 44 to 121 IU/L)
- Total bilirubin: 1.7 mg/dL (reference range 0.1 to 1.2 mg/dL)

From Taylor J. P., et al. (1988). Serological evidence of possible human infection with *Ehrlichia* in Texas. *The Journal of Infectious Diseases*, 158, 217.

Causes

Members of the genera *Ehrlichia* and *Anaplasma* are the most important pathogens in the family Anaplasmataceae. *Ehrlichiosis* was first noted to cause lethal infection in dogs in the 1930s. Postmortem examination revealed rickettsial-like inclusions in the monocytes. The bacteria were named *Rickettsia canis*. They differ from other rickettsiae in that they multiply in the phagosomes of host leukocytes and not in the cytoplasm of endothelial cells. In addition, they do not appear to be transmitted transovarially in ticks; however, transstadial transmission is known to occur. Because of these differences, they were reclassified into the new genus *Ehrlichia* in 1945. They were eventually named *Ehrlichia chaffeensis*. Ehrlichiae, like chlamydiae, possess an infective form known as the *elementary body*,

which replicates in the phagosome. As the bacteria divide, they develop **morulae** (mulberry-like bodies; see Fig. 24.10). As the host cell ruptures, the morulae break into many individual elementary bodies that continue the infective cycle.

Epidemiology

Ehrlichiosis became reportable to the CDC in 1999. It is a seasonal disease, with the majority of cases occurring during the summer months of June and July. *E. chaffeensis* causes **human monocytic ehrlichiosis (HME)**. The infection occurs worldwide. In the United States, most cases are found in the southeastern and southcentral states as well as in the mid-Atlantic states. Fewer than 2000 cases have been definitively or presumptively identified since the disease description in 1986; however, cases may be underreported. Natural hosts of the organism include dogs, deer, and humans, with the lone star tick (*Amblyomma americanum*) being the primary vector.

Anaplasma phagocytophilum, formerly known as *Ehrlichia phagocytophilum*, causes a disease now referred to as **human granulocytic anaplasmosis (HGA)**. In 1994, molecular amplification and DNA sequencing showed that the causative agent of HGA was distinct from *E. chaffeensis*. From 2015 to 2019, roughly 3500 to 5700 cases were reported annually; like HME, diseases are probably underreported. Deer, rodents, horses, cattle, and humans are natural hosts. Tick vectors include *Ixodes scapularis* and *I. pacificus*.

Clinical manifestations

HME and HGA cases are similar clinically, and many patients may experience asymptomatic infection. The organisms have an incubation period of 5 to 10 days. Disease is clinically variable, but most patients have a moderately severe febrile illness. The most frequent manifestations are malaise (94%), fever (92%), myalgia (77%), and headache (75%). A few patients have arthralgia or involvement of the gastrointestinal tract (nausea, vomiting, diarrhea), respiratory tract (cough, pulmonary infiltrates, acute respiratory distress syndrome), liver, or CNS. Rash is observed in about 6% of patients. As many as 60% of pediatric patients infected by *E. chaffeensis* have a rash, although adults rarely experience a rash. Patients may also have evidence of leukopenia, thrombocytopenia, and elevated liver enzyme levels. Patients can experience severe complications, including illness similar to toxic shock-like syndrome, CNS involvement, and adult respiratory distress syndrome. Mortality rates are approximately 2% to 3%, but case severity may be increased in patients with impaired splenic function.

Case check 40.3

Diagnosis of ehrlichiosis and anaplasmosis is complicated because patients may not remember or know that they were bitten by an arthropod vector, and many of them present with non-specific symptoms. In addition, many of these causative agents are difficult or impossible to grow in culture and therefore may be detected only by using serology or other assays, which may be difficult to interpret. As a result, many of the illnesses in this category may be misdiagnosed, and population data, including prevalence and incidence of these diseases, may be grossly underestimated.

Trypanosomiasis

Cause

Trypanosomiasis is caused by flagellate parasites in the genus *Trypanosoma*. Trypanosomiasis is notable for causing Chagas disease (*Trypanosoma cruzi*) in South, Central, and North America and African trypanosomiasis, or sleeping sickness (*Trypanosoma brucei*). Kissing bugs (*Triatomine* spp.) are the vectors of *T. cruzi* and tsetse flies (*Glossina* spp.) the vector of *T. brucei*. The World Health Organization reported 750 cases of African trypanosomiasis in 2021, a 95% reduction compared to 2001. However, the World Health Organization estimates that 6 to 7 million people are currently infected with *T. cruzi*.

Life cycle

Vectors develop trypanosomiasis when they take a blood meal from an infected animal host. *Trypanosoma* multiply in the gut of the vector, eventually reaching the intestinal tract in kissing bugs or the salivary glands in tsetse flies. *T. cruzi* is passed to the host through the feces of kissing bugs. Kissing bugs feed on a host through a piercing sucking mouthpart similar to other hemipterans. While feeding, the kissing bug becomes engorged with blood and will excrete waste on the host. After feeding, the bite site becomes irritated, causing the host to scratch. Infection occurs when the feces come in contact with the bite site. *T. brucei* is passed to the host through the saliva of tsetse flies. A tsetse fly uses a stylet-like appendage to pierce the host's skin and draw blood. It then uses its spongelike mouthparts to soak up the blood. While feeding, the fly will excrete infected saliva into the host's wound, causing infection.

Clinical manifestations

African trypanosomiasis has two stages. Initially this disease manifests like many others discussed in this chapter with fever, headaches, enlarged lymph nodes, and joint pain. Eventually the parasites cross the blood-brain barrier and infect the CNS. This stage is known as the *neurologic* stage. Symptoms include confusion, sensory disturbances, lack of coordination, and changes in behavior. Disturbance of the sleep cycle is a hallmark of this disease.

The acute phase of Chagas disease has many of the same symptoms as those discussed in the first stage of African trypanosomiasis, with the addition of nausea, diarrhea, vomiting, loss of appetite, and enlargement of the liver or spleen. In certain individuals, eyelid swelling will occur if the bite and infection occurred near the eyes. These symptoms will pass. If left untreated, Chagas progresses into the chronic phase over a period of a couple decades. Symptoms can include stomach pain, constipation from an enlarged colon, difficulty swallowing caused by an enlarged esophagus, irregular heartbeat, heart failure, and sudden cardiac arrest.

glands and is transmitted by biting to other animals. Humans can also acquire infection by inhalation, which can be the case in bat caves. Other infections have been linked to transplanted tissue such as the cornea.

After the bite, viruses replicate locally for several weeks to months. However, the virus preferentially infects nerve cells. Viruses move along the peripheral nerves to the spinal cord. From here, the virus moves rapidly to the brain. Invasion of the brain produces encephalitis. Using afferent nerves, the virus moves to highly innervated tissue such as the scalp, salivary glands, retina, cornea, and nasal mucosa. The prodromal stage of rabies includes nonspecific symptoms like pain and paresthesia at the bite site, fatigue, and anorexia. After a period of 2 to 10 days, the neurologic signs begin: disorientation, hallucinations, hyperexcitability, difficulty swallowing, and the classic rabies symptom, hydrophobia. Less than 20% of patients exhibit paralysis. There is no specific antiviral therapy, and the disease is nearly always fatal.

Diagnosis is made based on history of animal contact, although in many cases no such history is recalled by the patient or family members. Skin sample taken from the nape of the neck along the hairline and saliva are recommended for viral detection. The direct fluorescent antibody test is the standard antigen detection method for tissue. Reverse transcriptase polymerase chain reaction is performed on saliva or tissue. Virus-specific antibodies can be detected in serum and CSF. The disease is sometimes diagnosed postmortem using tissue taken from the CNS.

In 2019, first encountered in Wuhan, China, severe acute respiratory syndrome–coronavirus-2 (SARS-CoV-2) was identified as the cause of a coronavirus-associated acute respiratory disease outbreak. The disease, now known as Coronavirus Disease 2019 (COVID-19), rapidly spread worldwide and was declared a pandemic by the World Health Organization in March 2020. The CDC reported the first person in the United States to die from COVID-19 on February 20, 2020. By July 2022, the World Health Organization reported that the COVID-19 pandemic caused over 550,000,000 confirmed cases and over 6,000,000 deaths. For the same period, the CDC reported over 87,000,000 U.S. cases with over 1,000,000 deaths. Researchers believe that SARS-CoV-2 has zoonotic origins, possibly emerging from a bat-borne or pangolin-borne virus because of its close genetic similarity to these coronaviruses.

A worldwide outbreak of monkeypox began in 2022 and was declared a Public Health Emergency of International Concern by the World Health Organization in July 2022. Before the outbreak, most cases were linked to international travel or imported animals. This previously rare disease was first described in monkey colonies used for research. However, the actual source of the virus remains unknown. African rodents may transmit the disease to humans. The first case of human monkeypox was described in 1970.

Chapter 29 in this book discuss the following viral zoonotic agents: Lake Victoria Marburg virus; Zaire, Reston, Sudan, and Tai Forest Ebola viruses; Rift Valley fever virus; henipaviruses; SARS-associated coronavirus; West Nile virus; and HPAI virus. Hepatitis E virus (HEV) is transmitted via the fecal-oral route. Cattle, rats, sheep, monkeys, goats, and especially pigs are vulnerable to HEV infection. In Nepal, most outbreaks have occurred after monsoon rains and flooding, fecal contamination of well water, and untreated raw sewage entering city water supplies.

Viral zoonotic diseases

Rabies, caused by the rhabdovirus, is a classic zoonosis. It is typically transmitted by the bite of infected animals, predominantly mammals, such as bats, cats, dogs, foxes, raccoons, and skunks. The virus infects the CNS of these animals, triggering aggressive behavior. The virus also inhabits the salivary

Emerging zoonoses

In recent years, the significance of zoonotic infections has continued to grow in prominence because of the emergence of several large-scale outbreaks in humans and animals. Although not all-inclusive, these have included the 2003 SARS, the low pathogenic avian influenza A virus subtype H7N2, the 2004 highly pathogenic avian influenza (HPAI) A virus subtype H5N1, the 2009 influenza A virus subtype H1N1 (swine flu), the 2010 *Escherichia coli* 0104:H4, COVID-19, and the 2022 monkeypox outbreak outbreaks.

The worldwide economic losses attributed to zoonotic diseases during the past decade were estimated at over \$200 billion before the ongoing COVID-19 pandemic. The social and economic impact of the pandemic on global gross domestic product growth is massive. In the United States alone, the total economic cost of the SARS-CoV-2 pandemic was estimated at trillions of dollars with lost jobs, service industries shattered, and education compromised. In addition, the emergence of novel zoonotic diseases has placed an undue burden on the medical industry because of the intrinsic difficulties associated with diagnosis, care, and treatment of patients.

The number and frequency of zoonotic disease outbreaks are increasing, which has sparked international interest and has resulted in a number of workshops, committees, and scientific groups sponsored by prestigious organizations, including the CDC, the U.S. Agency for International Development, the U.S. Department of Agriculture, the U.S. Department of Defense–Global Emerging Infections Surveillance and Response System, the World Health Organization, the Food and Agriculture Organization of the United Nations, the Office International des Epizooties (World Health Organization for Animal Health), and the Pan American Health Organization. The purpose of these organizations is to determine the root cause of these increases, identify strategies to minimize their economic and public health impact, and identify potential emerging zoonotic disease threats.

Although a number of factors have attributed to the increase in emerging and reemerging zoonoses, explosive population growth appears to be the most significant. According to statistics from the United Nations, the world population has more than doubled in the past 50 years (from 2.5 billion to 6.5 billion) and continues to increase at a rate of 1.7% per year. This increase has led to changes in land use, including deforestation of farmland and pastures, urbanization, and use of raw materials, all of which force humans and domestic animals to move into previously unpopulated areas and wild animals to change their migration routes and share their habitat with humans. Population growth also increases the demand for animal protein, forcing poultry, livestock, and animal products to be transported from rural areas to more populous areas and increases international trade of these commodities. The net result of all of these changes is increased interaction and microbial exchange among humans, domestic animals, and wild animals. It also provides a mechanism for the global spread of novel agents as they jump from species to species.

It is widely accepted that the key to reducing the impact of emerging zoonoses is global surveillance. However, just as the costs attributed to zoonotic outbreaks are staggering, so

are those associated with establishing and maintaining the required surveillance network. It is estimated that an investment of \$800 million per year would be required to support the required global surveillance and early response capabilities, including infrastructure building, capacity building, and research and development. In addition to these costs, there are two other significant roadblocks to implementation—garnering international cooperation and convincing resource-rich countries to provide developing nations with the required monetary resources so efforts can be focused in areas with the highest potential for emerging zoonotic infections.

In recent years, much emphasis has been placed on preparedness for influenza A virus pandemics. This has largely occurred because of the ability of influenza A virus to mutate and reassort with other influenza viruses, including those from other host species; the potential for the creation of a novel strain; and the efficiency of respiratory virus transmission. These abilities were highlighted by the 1918 influenza A virus subtype H1N1 (Spanish flu) pandemic, which killed between 50 million and 150 million people (3% of the world's population at the time). This explains the amount of concern generated by the recent emergence of two novel strains: the HPAI A virus subtype H5N1 (avian flu) in poultry and the 2009 influenza A virus subtype H1N1 (swine flu). Fortunately, both viruses lacked the key components necessary to make them as devastating as the 1918 strain. Swine flu could be transmitted very efficiently as demonstrated by the pandemic it caused, but it had a low mortality rate. However, avian flu has a very high mortality rate but currently lacks the ability for efficient person-to-person transmission. On the other hand, another respiratory virus, SARS-CoV-2 (COVID-19) was proven to be highly infectious and easily transmitted from person to person, and although most individuals are asymptomatic or have mild symptoms, those with certain medical conditions often progress to severe, life-threatening, and fatal illness.

Avian and swine flu as well as SARS are examples of **emerging zoonoses**. The term implies the discovery of a new agent, discovery of a known agent that has moved to a new geographic location, discovery of a known pathogen that has become drug resistant, or some other modification. These emerging zoonoses can cause human susceptibility to novel agents that jump from animal populations into human populations. By definition, some of the zoonotic agents already discussed fall into the category of emerging pathogens, including *B. burgdorferi*, *E. chaffeensis*, *A. phagocytophilum*, *B. henselae*, and *T. cruzi*. Emerging zoonotic diseases are of concern and highlight the necessity for continued pandemic surveillance, planning, and antiviral stockpiling.

Case check 40.4

Outbreaks of novel zoonotic diseases are becoming increasingly common, and the economic losses associated with them are staggering. Countermeasures to prevent them or reduce their impact are complicated and require a significant capital investment. However, based on recent data, the estimated cost associated with developing prevention capability is several orders of magnitude less than the economic toll attributed to outbreak responses over the past decade.

POINTS TO REMEMBER

- Testing for zoonotic infections represent a significant percentage of the workload in a clinical microbiology laboratory.
- Animal exposure and insect bites are important clues about possible causes of a patient's infection.
- Zoonotic agents can be bacterial or viral as well as parasitic or mycotic.
- Not all zoonotic infections are contagious. In several zoonotic infections, the pathogens spread efficiently to humans but do not spread easily from person to person. Many zoonotic infections are arthropod-borne.
- For the past 30 years, emerging infections have been recorded, including the discovery of previously unknown pathogens. Of these, 75% have a zoonotic origin.

LEARNING ASSESSMENT QUESTIONS

- Erythema migrans (EM) is a rash associated with which zoonotic infection?
- Late persistent Lyme borreliosis is usually characterized by which type of clinical manifestation?
- Which two animals are most often associated with human cases of pasteurellosis?
- Which two preexisting medical conditions increase the risk of *Capnocytophaga canimorsus* infection in humans?
- Which organism is most likely associated with cat scratch disease (CSD)? What is another organism that can also cause CSD?
- Which toxins are responsible for life-threatening edema in pulmonary anthrax?
- Which four species of brucellae are pathogenic to humans, and what are the normal hosts for these organisms?
- What are the differences between icteric and anicteric leptospirosis?
- Which zoonotic agents are responsible for causing human granulocytic anaplasmosis (HGA) and human monocytic ehrlichiosis (HME)? What underlying medical issue may increase the severity of these diseases?
- Which species are included in the typhus group of the genus *Rickettsia*?
- Describe the pathogenesis of Rocky Mountain spotted fever.
- Define emerging zoonotic disease. What is the worldwide cost attributed to zoonotic outbreaks in the past decade?
- Which of the following is not a clinical manifestation of pasteurellosis?
 - Cellulitis
 - Corneal ulcers
 - Stomach ulcers
 - Pericarditis
- Which genera of tick includes the primary vectors of *Borrelia burgdorferi*?
 - Dermacentor*
 - Amblyomma*
 - Rhipicephalus*
 - Ixodes*
- In which zoonotic illness are humans the primary reservoir?
 - African trypanosomiasis
 - Pasteurellosis
 - Cat scratch disease
 - Plague
- Which zoonoses have an eschar associated with them?
 - Lyme borreliosis and rickettsial disease
 - Rickettsia disease and anthrax
 - Cat scratch fever and leptospirosis
 - Anthrax and trypanosomiasis
- Which of the following is *not* a manifestation of anthrax?
 - Cutaneous
 - Pulmonary
 - Intestinal
 - Subcutaneous
- Which of the following is *not* a vector or vehicle of transmission for tularemia?
 - Animal bites
 - Aerosols
 - Contaminated blood
 - Contaminated soil
- What is another name for Weils syndrome?
 - Rocky Mountain spotted fever
 - Icteric leptospirosis
 - Cutaneous anthrax
 - African trypanosomiasis
- Which typhus is associated with chiggers?
 - Murine typhus
 - Epidemic typhus
 - Scrub typhus
 - Both a and c
- Which typhus is associated with Brill-Zinsser disease?
 - Epidemic typhus
 - Scrub typhus
 - Murine typhus
 - Both b and c
- Which of the following is a vector of African trypanosomiasis?
 - Kissing bug
 - Tick
 - Tsetse fly
 - Flea

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Describe the most important ocular structures and their functions.
2. Discuss the role of normal biota in protecting ocular structures.
3. Describe the most common ocular infections and their causative agents.
4. Describe the pathogenesis of the various eye pathogens presented in this chapter.
5. Associate the sources and risk factors for particular pathogens causing ocular infections.
6. Explain the virulence mechanisms associated with ocular pathogenic organisms.
7. Justify the laboratory procedures for recovery and identification of ocular pathogens.
8. Compare the administration methods for antimicrobials used in the treatment of ocular infections with those used in the treatment of other types of infections.

KEY TERMS

Blepharitis	Keratitis
Canaliculitis	Keratoconjunctivitis
Conjunctivitis	Orbital cellulitis
Dacryoadenitis	Preseptal cellulitis
Dacryocystitis	Scleritis
Endophthalmitis	Stye

Case in point

A healthy 20-year-old female patient with no history of ocular disease started wearing disposable contact lenses 3 months prior. She replaced them every 7 to 10 days. The patient developed blurred vision, pain, photophobia, and redness in her right eye during the 12th week. An examination revealed conjunctival edema and four small corneal ulcers with a green, mucopurulent discharge. Smears for Gram and Giemsa stains were prepared from the discharge. Cultures were performed from corneal scrapings and from the contact lens and solution.

Issues to consider

After reading the patient's case history, consider:

- The role that the technique for handling, insertion, and removal of a contact lens may have in establishing ocular infections
- The need for rapid diagnosis in this case
- Common pathogens involved in this type of infection

Any organism capable of gaining entrance to ocular structures can cause disease. Ocular infections range from relatively mild, self-limiting **conjunctivitis** (inflammation of the conjunctiva) and **blepharitis** (inflammation of the eyelids) to the more severe and sight-threatening conditions **keratitis** (inflammation of the cornea) and **endophthalmitis** (inflammation of the inside lining and cavities of the eyes). The surrounding soft tissues, sclera, lacrimal system, and bony orbit are also subject to microbial invasion. Bacteria, fungi, viruses, and protozoa all play prominent roles in the pathogenesis of ocular disease. The selection of specific microbiological procedures is dependent on the severity of symptoms, site of infection, and likely pathogen.

General concepts related to ocular infections

Ocular structures

Fig. 41.1 depicts the most important ocular structures. The visual system is composed of the eyeball (globe), muscles, fat, nerves, orbital bones, and neural pathways that carry electric impulses that are converted into vision. This system does not actually “see”; instead, it acts as a receptor for sensory light stimuli that are translated into neural impulses by the retina and then processed by the occipital lobe of the brain. In a sense, the eye is a frontal extension of the brain.

The conjunctiva is a mucous membrane covering the inside lining of the eyelids and white covering of the eyeballs (sclera). It is similar to the membranes in the mouth and nose, and it constitutes the front line of defense against invading organisms. The tears that keep the conjunctiva moist contain many enzymes and other factors (e.g., immunoglobulin A [IgA], phospholipase A₂, complement proteins, lysozyme, lactoferrin, mucins) that protect the conjunctiva from microbial invasion.

The eyelids are thin elastic layers or folds of tissue that help protect the structures of the orbit. They are the thinnest skin covering in the body. The blinking action of the eyelids and conjunctivae help keep the cornea and sclera lubricated and sweeps away debris and potential pathogens. The eyelashes act as a filtering and monitoring system that alerts the brain to potentially harmful agents.

The cornea is considered the window of the eye. Its function is similar to that of a crystal on a wristwatch. The internal ocular structures can be viewed through the cornea. The function of the curved corneal surface is to refract, collect, and focus light onto the retina. A layer of tears (the tear film) blankets the cornea to provide optical clarity, lubrication, and nutrition. Many free nerve endings are located in the corneal epithelium. When there is a break in or an injury to the

Fig. 41.1 Common ocular structures. (Modified from Jones, D. B., et al. (1981). *Laboratory diagnosis of ocular infections*. In J. A. Washington (Ed.), Cumitech 13. Washington, DC: American Society for Microbiology.)

epithelium, the patient usually complains of considerable pain. Infections and injury to the cornea are considered true ocular emergencies.

Ocular microbial biota

Coagulase-negative staphylococci and *Corynebacterium* spp. make up 80% to 90% of the indigenous microbiota recovered from noninflamed eyes. However, depending on the age of the individual, season, location, and underlying conditions, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and other potential pathogens may be recovered from noninfected eyes (Table 41.1). The presence of a resident biota on the conjunctivae and eyelids can be a protective mechanism, inhibiting invasion and colonization by more harmful organisms. The normal resident conjunctival and eyelid microbiota change with age.

The distinction between indigenous microbiota and ocular pathogens can be blurred. Coagulase-negative staphylococci, *Cutibacterium acnes*, and *S. aureus* are responsible for many intraocular and corneal infections. The presence of biomaterials and the use of steroids, antimicrobials, and contact lenses can predispose ocular tissues to infection with indigenous microbiota. In the United States, an estimated 38

Table 41.1 Ocular resident biota from noninflamed eyes

Organisms ^a	Incidence (%)
Coagulase-negative staphylococci ^b	34–94
<i>Cutibacterium acnes</i> ^b	40–86
<i>Corynebacterium</i> spp. ^b	3–83
<i>Staphylococcus aureus</i>	0–30
<i>Haemophilus influenzae</i>	0–25
<i>Micrococcus</i> spp.	2–22
<i>Streptococcus pneumoniae</i>	0–5
Viridans group streptococci	0–12
Gram-negative rods (<i>Proteus</i> spp., <i>Escherichia coli</i> , <i>Klebsiella pneumoniae</i> , <i>Enterobacter</i> spp.)	0–5
<i>Moraxella</i> spp. (including <i>Moraxella catarrhalis</i>)	0–3
<i>Bacillus</i> spp. (<i>Bacillus cereus</i> , <i>Bacillus subtilis</i>)	0–4
<i>Neisseria</i> spp. (<i>Neisseria sicca</i> , <i>Neisseria flavescens</i>)	0–7
Fungi (any saprophyte, depends on locale)	0–24
Anaerobic biota other than <i>Cutibacterium acnes</i> , <i>Peptostreptococcus</i> spp., <i>Bacteroides</i> spp., <i>Clostridium</i> spp.	1–5
β-Hemolytic streptococci, including <i>Streptococcus pyogenes</i>	0–3
Sterile	9–47

^aSource is usually the conjunctivae and eyelids; the organism isolated depends on the age of the patient, geographic locale, season, previous and current therapy, and underlying condition (e.g., diabetes, epithelial disease). Most common isolates usually reflect that of the surrounding tissue.

^bCan also cause mild to severe disease in immunocompromised patients.

million individuals wear contact lenses. Although contact lenses pose a substantial risk for eye infections, such infections are relatively uncommon in individuals wearing them. Daily disposable contact lenses pose a lower risk of infection than reusable lenses. The presence of an unapparent biofilm (see [Chapter 31](#)) in the storage case has been cited as a source of contact lens contamination. In addition, the antimicrobial agents used in storage solutions might not be effective against some strains of *Pseudomonas aeruginosa* or *Acanthamoeba* spp.

Case check 41.1

The patient in the Case in Point presented with symptoms suggestive of conjunctivitis and keratitis. She is at increased risk for this type of infection because of the use of contact lenses. It is important that individuals use proper hand hygiene while inserting and removing contact lenses.

Organisms may be recovered from the conjunctival sac and eyelids without causing infection. Quantitative ocular cultures have been used to establish a threshold to differentiate between infection and colonization. A threshold is set for each organism, and infection is established when organisms reach or exceed the threshold number. It is important

to remember that once the epithelium of the conjunctiva or cornea is compromised, any organism gaining entrance can result in disease, and the presence of any amount of organisms in what should be a sterile site is indicative of infection.

Host protective mechanisms

Because of their location, external ocular structures and surfaces, such as the conjunctivae and cornea, are frequently challenged by a variety of microorganisms. Whether an infection or damage ensues depends on the structure, immune status, and response of the host; integrity of the underlying tissues; and pathogenesis of the invading organism. Protection of ocular structures is partly supported by a defense system that includes local and systemic, specific and nonspecific, and humoral and cellular mechanisms that join to prevent microbial colonization or invasion. Their protection is further supported by an anatomic arrangement that leaves the inner ocular structures well sequestered. The intact epithelia of the eyelid, conjunctiva, and cornea provide a protective barrier against invasion by most microbes.

Tears contain high concentrations of IgA, lysozyme, and lactoferrin. All three have antimicrobial properties. IgA coats bacteria, aids in complement fixation and phagocytosis, and can inhibit colonization by pathogens. Lysozyme attacks bacterial cell walls, primarily those of gram-positive bacteria, by splitting bonds in the peptidoglycan layer. Lactoferrin inhibits the growth of bacteria by competing for and binding to iron. Secretory phospholipase A₂ has activity against gram-positive bacteria by binding to the bacterial cell surface and killing the cell by lipolytic enzymatic activity. The blinking action of the eyelids and flow of tears also protect the eye from infection by removing bacteria and debris from the ocular surface. Cooler ocular surface temperatures can inhibit the growth of many microorganisms.

Risk factors associated with ocular infections include age, sex, race, socioeconomic status, behavior, geographic location, occupation, and underlying disease. Acute bacterial and viral conjunctivitis occur more frequently in childhood, whereas chronic conjunctivitis and varicella-zoster virus (VZV) conjunctivitis occur most frequently in older adults. *S. aureus* and *Candida albicans* are usually recovered from patients with keratitis in cooler climates; *P. aeruginosa* and filamentous fungi are the main pathogens recovered from patients in warmer climates. Fungal or traumatic keratitis has been diagnosed in farmers and agricultural workers. *S. pneumoniae* and *Moraxella* spp. are recovered from people with alcoholism and those who are homeless. Women are more likely than men to have trachoma, a serious eye infection caused by *Chlamydia trachomatis*, whereas chlamydial inclusion conjunctivitis is most often identified in men.

Virulence factors of ocular pathogenic organisms

Several microbes can penetrate the intact epithelium of the conjunctiva or cornea, including *Neisseria gonorrhoeae*, *Neisseria meningitidis*, *S. pneumoniae*, *Listeria monocytogenes*, and *Corynebacterium diphtheriae*. For most other microbes to enter and establish disease, a break must occur in the protective epithelial barrier. Once the intact epithelium is breached (e.g., by trauma, by insertion or removal of a contact lens), an

intrusion by pathogenic and saprophytic organisms can occur. Many ocular pathogens possess adhesions and enzymes that aid in adherence, multiplication, and dissemination in ocular tissues. *S. aureus*, *P. aeruginosa*, and coagulase-negative staphylococci may persist in ocular tissue or biomaterials in a biofilm, which protects them from host defenses, antimicrobial agents, and eradication. Penetrating eye trauma caused by a soil-contaminated object can result in *Bacillus cereus* infection that frequently results in complete loss of the eye within 48 hours.

When an infection has started in one layer of the eye, spread to adjacent layers and tissues can occur rapidly. Dissemination of the infection within ocular structures can result in devastating and permanent damage to the functional integrity of the eye. Box 41.1 lists organisms recovered from ocular infections. Any organism that can gain entrance to the

internal structures of the eye is capable of causing infection. The list is long and varied. Organisms considered contaminants or colonizers are the most frequent pathogens. Many systemic illnesses, such as tuberculosis, syphilis, diabetes, hypertension, and acquired immunodeficiency syndrome (AIDS), can also have ocular symptoms. The organism most likely to be encountered depends on the season, climate, age of the patient, and underlying disease.

Infections of the conjunctivae

Conjunctivitis is the most common ocular complaint. It includes all age groups and occurs worldwide. An estimated 6 million people in the United States develop conjunctivitis annually,

BOX 41.1 Microorganisms associated with ocular infectious disease

Bacteria

Gram-negative (aerobic)

Alcaligenes spp.
Acinetobacter spp.
Aggregatibacter actinomycetemcomitans
Achromobacter xylosoxidans
Aeromonas hydrophila
Bartonella henselae
Borrelia tularensis
Brucella spp.
Capnocytophaga spp.
Eikenella corrodens
Enterobacterales
Flavobacterium spp.
Francisella tularensis
Haemophilus aegyptius
Haemophilus influenzae
Haemophilus parainfluenzae
Kingella spp.
Neisseria gonorrhoeae
Neisseria meningitidis
Moraxella catarrhalis
Moraxella lacunata
Pseudomonas aeruginosa

Gram-negative (anaerobic)

Bacteroides spp.
Fusobacterium spp.
Prevotella spp.

Gram-positive (aerobic)

Bacillus cereus
Bacillus spp.
 β -Hemolytic streptococci (A, B, C, F, G)
Corynebacterium spp.
Enterococcus faecalis
Listeria monocytogenes
Micrococcus spp.
Staphylococcus aureus
Staphylococcus epidermidis and other coagulase-negative staphylococci
Streptococcus pneumoniae
Viridans group streptococci

Gram-positive (anaerobic)

Actinomyces israelii
Actinomyces spp.

Clostridium spp.
Peptostreptococcus spp.
Cutibacterium acnes
Propionibacterium propionicus

Aerobic actinomycetes

Nocardia spp.
Streptomyces spp.

Chlamydia and similar organisms

Chlamydia trachomatis
Chlamydia pneumoniae
Chlamydia psittaci
Coxiella burnetii

Mycobacteria

Mycobacterium abscessus
Mycobacterium avium complex
Mycobacterium chelonae
Mycobacterium fortuitum
Mycobacterium gordonae
Mycobacterium leprae
Mycobacterium mucogenicum
Mycobacterium nonchromogenicum
Mycobacterium triviale
Mycobacterium tuberculosis

Parasites

Acanthamoeba spp.
Ascaris lumbricoides
Leishmania spp.
Loa loa
Microsporidia spp.
Onchocerca volvulus
Phthirus pubis
Taenia solium
Toxocara canis and *Toxocara cati*
Toxoplasma gondii
Trichinella spiralis
Trypanosoma spp.
Vahlkampfi spp.
Wuchereria bancrofti

Viruses

Adenoviruses
Coxsackieviruses
Cytomegalovirus

Enteroviruses
Epstein-Barr virus
Herpes simplex virus types 1 and 2
Human herpesviruses 6, 7, and 8
Human immunodeficiency virus
Human papillomavirus
Influenza virus
Measles virus
Molluscum contagiosum virus
Mumps virus
Vaccinia virus
Varicella-zoster virus

Fungi

Molds

Acremonium spp.
Alternaria spp.
Aspergillus spp.
Bipolaris spp.
Blastomyces dermatitidis
Coccidioides immitis
Cladosporium spp.
Colletotrichum spp.
Curvularia spp.
Drechslera spp.
Exophiala jeanselmei
Fusarium spp. (*Fusarium oxysporum* and *Fusarium solani* most common)
Histoplasma capsulatum
Paecilomyces spp.
Penicillium spp.
Phialophora spp.
Mucor spp.
Rhizopus spp.
Scedosporium apiospermum
Sporothrix schenckii
Volutella spp.

Yeasts

Candida albicans
Candida spp., other than *C. albicans*
Cryptococcus neoformans
Rhodococcus spp.
Torulopsis glabrata

and 1% of all primary care visits are related to this condition. Symptoms may include itching, tearing, a foreign-body sensation, discharge (purulent or watery), and hyperemia, or increased blood flow resulting in “red eye.” Red eye constitutes more than 50% of office visits to ophthalmologists and is the most common ocular reason for microbiological evaluation.

Conjunctivitis may be acute, hyperacute, subacute, or chronic. Viruses are the most common cause of infectious conjunctivitis, and bacteria are the second most common cause. Fungal and parasitic infections are seen less frequently (Box 41.2). Uncomplicated acute viral conjunctivitis is generally self-limiting and does not require treatment. Infections by *N. gonorrhoeae*, *C. trachomatis*, and other bacteria should be treated. Treatment may be topical, except for gonococcal and chlamydial infection, which should be treated with systemic antimicrobials. Corneal involvement may follow conjunctivitis and compromise vision. Chronic infections are more difficult to manage and result in long-term ocular morbidity and compromised vision. Up to 40% of the U.S. population experiences allergic conjunctivitis, but the majority of these individuals do not seek treatment.

Bacteria

Acute bacterial conjunctivitis

A statistically significant positive correlation was reported between conjunctivitis and weekly sunshine duration and weekly average temperatures at a U.S. hospital. This indicates

that more cases of conjunctivitis occur in warmer weather or that patients are more likely to seek treatment in warmer weather. Other studies have reported that cases of bacterial conjunctivitis peak during December to April, whereas more cases of viral conjunctivitis occur in the summer. Staphylococci, in particular *S. aureus*, are the most frequently isolated pathogens, followed by *S. pneumoniae* and *H. influenzae*. In children with acute conjunctivitis, *H. influenzae*, *S. pneumoniae*, and *Moraxella catarrhalis* are the most frequently isolated organisms. *N. gonorrhoeae* (Fig. 41.2) and *C. trachomatis* cause a hyperacute conjunctivitis that produces large

Fig. 41.2 Gonococcal conjunctivitis. Note the copious discharge in response to invasion by *Neisseria gonorrhoeae*.

BOX 41.2 Microorganisms associated with conjunctivitis

Bacteria

Gram-negative

Acinetobacter spp.
Bartonella henselae
 Enterobacterales (e.g., *Escherichia coli*, *Proteus mirabilis*,
Shigella spp.)
Francisella tularensis
Haemophilus influenzae
Haemophilus ducreyi
Moraxella catarrhalis
Moraxella lacunata
Neisseria gonorrhoeae
Neisseria meningitidis
Pseudomonas aeruginosa
Yersinia enterocolitica

Gram-positive

β -Hemolytic streptococci (A, B, C, G)
Corynebacterium diphtheriae
Corynebacterium spp.
Listeria monocytogenes
Mycobacterium tuberculosis
Staphylococcus aureus
Staphylococcus epidermidis
Streptococcus pneumoniae
 Viridans group streptococci

Chlamydia

Chlamydia pneumoniae

Chlamydia psittaci

Chlamydia trachomatis

Viruses

Adenoviruses
 Human coronaviruses
 Herpesviruses (1–8)
 Influenza virus
 Paramyxoviruses (measles, mumps, and Newcastle disease viruses)
 Picornaviruses (echovirus, enterovirus, coxsackievirus, poliovirus)
 Poxviruses (molluscum contagiosum virus and vaccinia virus)

Fungi (rare)

Candida spp.
Coccidioides immitis
Rhinosporidium seeberi
Sporothrix schenckii

Parasites (rare)

Ascaris lumbricoides
 Fly larvae (*Oestrus ovis*, myiasis)
Loa loa
 Microsporidia

Pthirus pubis
Taenia solium
Trichinella spiralis
Toxocara canis
Wuchereria bancrofti

amounts of exudate. Infants can acquire *N. gonorrhoeae* as they pass through an infected birth canal. Symptoms may appear within 5 to 7 days after exposure to the pathogen. It is believed that adults acquire gonococcal conjunctivitis through self-inoculation from a genital infection. Meningococcal conjunctivitis may result from contiguous spread from the respiratory tract.

Chronic bacterial conjunctivitis

The causative agents in chronic conjunctivitis, defined as cases lasting longer than 4 weeks, are less clear. The microorganisms that have been isolated most frequently include *S. aureus*, *Moraxella lacunata*, and enteric bacteria. Coagulase-negative staphylococci and *C. acnes* have been seen less frequently. Chronic conjunctivitis may result from interplay between the organism and an aggressive ocular immune response. Bacterial conjunctivitis can also be caused by instillation of contaminated cosmetics or medications. The organisms encountered in such infections are *S. aureus*, *Staphylococcus epidermidis*, *Corynebacterium* spp., *P. aeruginosa*, and *Proteus mirabilis*. Allergic and chemical conjunctivitis can sometimes be confused with microbial infections.

Laboratory diagnosis

Laboratory tests can assist in differentiating acute, allergic, and chronic conjunctivitis. Conjunctival scrapings are collected using a Kimura spatula, blade, or sterile swab and plated directly onto culture media and slides. Routine stains (e.g., Gram, Giemsa) and culture should reveal the causative agent in most acute cases. Smears and culture specimens should be collected in all cases of purulent, membranous, or pseudomembranous conjunctivitis. Laboratory workup is mandatory for all cases of neonatal and infant conjunctivitis. Culture and examination of smears may be of less value in establishing the causative agent in chronic conjunctivitis.

Treatment

Many bacterial conjunctivitis cases are self-limiting and resolve without treatment. Antimicrobial agents can reduce symptoms and prevent secondary infections. Initial, empiric topical therapy is often sufficient. Therapy is then adjusted based on the organism isolated and antimicrobial susceptibility testing.

Chlamydial ocular infections

C. trachomatis causes a myriad of ocular infections, including neonatal conjunctivitis, inclusion conjunctivitis (Fig. 41.3A), and trachoma. Currently, 20 serotypes or serovars of *C. trachomatis* have been described, and specific serovars are associated with certain clinical manifestations. Trachoma, which is as old as recorded history, is usually caused by serovars A, B, Ba, or C, whereas serovars D to K are usually associated with oculogenital inclusion conjunctivitis.

Neonatal conjunctivitis becomes apparent within 8 to 10 days after birth. The infant is infected while traveling through the infected birth canal. *C. trachomatis* inclusion conjunctivitis can lead to pharyngitis, otitis media, and interstitial pneumonitis in the newborn. Chronic conjunctivitis with cornea involvement is a consequence of untreated or inadequately treated inclusion conjunctivitis. Trachoma is a leading cause of blindness worldwide. Regional variation exists in prevalence and severity. Worldwide, 1.9 million people have trachoma, and 200 million people live at risk of the disease. It is endemic in some of the poorest countries in Africa, Central and South America, Asia, Australia, and the Middle East. The initial conjunctivitis is follicular conjunctivitis, followed by repeated infections, which lead to scarring and blindness. Nasolacrimal duct obstruction and dacryocystitis (infection of the lacrimal sac caused by obstruction, usually seen in children) are complications that follow trachoma. Chronic conjunctivitis leading to scarring and chronic keratitis may follow trachoma and inclusion conjunctivitis. Blindness is irreversible.

The prevalence rates for ocular chlamydial infection parallel those of genital disease. In areas with high rates of sexually transmitted infections (STIs), ocular disease rates are also high. Populations with the highest incidence of disease include neonates and sexually active adolescents and adults. The incidence can range from 20% to 90%, depending on the age group. In areas with low rates of STIs, ocular chlamydial infection rates also are low.

Chlamydia pneumoniae was originally isolated from the conjunctiva of a child. Most adults will have antibodies against this organism. Acute ocular infections with this organism are rare. It has been isolated most often in lower respiratory tract infections.

Fig. 41.3 A, White spots on the conjunctiva represent pockets of *Chlamydia* organisms in tissue. B, Immunofluorescence stain of scrapings from neonatal conjunctivitis, confirming the presence of chlamydial elementary bodies.

Laboratory diagnosis

Direct detection of the chlamydial inclusions in scrapings or on impression cytology membranes is generally considered a sensitive method for confirming ocular *Chlamydia* infections (see Fig. 41.3B). *Chlamydia* inclusions can be seen using Giemsa-stained smears and fluorescent-labeled monoclonal antibodies. *C. trachomatis* and *C. pneumoniae* can be isolated in tissue culture using McCoy or human epithelial type 2 (HEp-2) cells. However, nonculture detection methods, such as polymerase chain reaction (PCR) assay, direct fluorescent antibody assay, and enzyme immunoassay (EIA), are more frequently used to detect ocular *Chlamydia* infections. Nucleic acid amplification tests (NAATs) are considered the methods of choice because of their high sensitivity and specificity.

Treatment

Although erythromycin is administered prophylactically to neonates to prevent eye infections caused by *C. trachomatis*, its efficacy is not clear. However, ocular prophylaxis with erythromycin prevents gonococcal ophthalmia, and it should be administered. Topical treatment alone is inadequate to treat eye infections caused by *C. trachomatis*. Current recommendations by the Centers for Disease Control and Prevention (CDC) for the treatment of ocular chlamydial infection are as follows:

- Adults: azithromycin, 1 g orally in a single dose; or doxycycline, 100 mg orally twice a day for 21 days
- Neonates: erythromycin, 50 mg/kg per day orally, in four daily doses for 14 days; or azithromycin, 20 mg/kg per day orally, one dose daily for 3 days

Viruses

Viral conjunctivitis is a commonly recognized ocular infectious disease. It may also present as an acute or chronic illness, ranging from a mild, self-limiting condition to a severe, destructive disease resulting in impaired vision. Corneal involvement often follows viral infection of the conjunctiva. Healthcare-associated transmission of adenoviruses can occur during ocular examinations because the virus can persist in optic solutions or ophthalmic equipment. Use of single-dose packages or sterile drops augmented with frequent hand-washing can reduce the risk of transmission to patients and health care providers. A tonometer, a device used to measure intraocular pressure, should be cleaned with alcohol, rinsed with sterile water, and allowed to dry. Patients exposed to contaminated body fluids, fomites, or vesicular fluids are at increased risk of infection with herpes simplex virus (HSV), VZV, or epidemic keratoconjunctivitis (EKC), an infection of the cornea and conjunctiva.

Acute viral conjunctivitis

Acute viral infections are attributed mainly to adenoviruses, herpesviruses, or enteroviruses. The adenoviruses are responsible for two distinct ocular viral syndromes, EKC and pharyngoconjunctival fever (PCF). EKC is contagious and associated with adenovirus types 8 and 19, but recovery of serovars 7, 9, 10, 11, 14, and 16 has also been documented. PCF is frequently caused by adenovirus type 3 and occasionally by serovars 1,

2, 4, 5, 6, 8, and 14. Both syndromes are self-limiting and have no specific treatment; PCF lasts about 10 days, and EKC lasts 3 to 4 weeks at most. EKC may be spread through direct contact, fomites, and, not uncommonly, health care providers. It is usually responsible for outbreaks in ophthalmic offices and clinics, school locker rooms, and college dormitories.

Acute hemorrhagic conjunctivitis (Fig. 41.4), or epidemic hemorrhagic conjunctivitis (EHC), is an acute, short-lived infection caused by enterovirus 70, coxsackievirus A24, and, on rare occasions, adenovirus type 11. The onset of symptoms usually occurs within 8 to 48 hours of exposure, with patients complaining of pain, sensitivity to light, copious tears, and subconjunctival hemorrhages. It is self-limiting and has no outlined treatment program. Recovery occurs within 5 to 7 days. Because EHC is highly contagious and easily spread from person to person, patients should be isolated until the condition has resolved.

HSV blepharoconjunctivitis is responsible for most severe ocular viral infections. This disease usually occurs in young children. It is important to distinguish between HSV and adenovirus because HSV can be treated with specific ocular antiviral medications, whereas adenovirus infection cannot. More than 90% of cases of HSV blepharoconjunctivitis are caused by HSV-1, but HSV-2 has been isolated from infants and adults. VZV may also cause conjunctivitis. This condition is usually a manifestation of the systemic disease chickenpox or a complication of herpes zoster ophthalmicus. Cytomegalovirus (CMV) can cause conjunctivitis when it becomes disseminated or is transmitted through tears from another patient. Epstein-Barr virus (EBV) conjunctivitis may result as a complication of infectious mononucleosis. Chronic viral conjunctivitis may result from molluscum contagiosum or vaccinia, a complication of smallpox vaccination.

Laboratory diagnosis

Conjunctival scrapings may be stained with fluorescent-labeled monoclonal antibodies to confirm infection with an ocular viral pathogen. NAATs are also available for several of the viral agents and are the preferred method. The most common pathogens may be grown in cell culture and serotyped with monoclonal antibodies or neutralization tests.

Fig. 41.4 Acute hemorrhagic conjunctivitis. The causative agent is usually enterovirus 70 or coxsackievirus A24. Other members of the enterovirus group may also be recovered. Note the heavy conjunctival hemorrhaging.

Treatment

Currently, there is no treatment for adenoviral and/or enteroviral ocular infections. Cold compresses may help alleviate some of the symptoms. Orally administered acyclovir/valacyclovir can be used to treat HSV and VZV infections.

Fungi

Although various fungi can be isolated from the uninflamed eye, fungal conjunctivitis is relatively rare. The organisms that have been recovered from fungal conjunctivitis are *Candida* spp. and *Sporothrix schenckii*. Systemic fungal infections caused by *Coccidioides immitis*, *Histoplasma capsulatum*, and *Cryptococcus neoformans* may extend to the conjunctival tissue and cause disease. To diagnose fungal conjunctivitis, the health care provider must have a high index of suspicion, and the laboratory must be alerted to ensure that the proper setup for recovery of these organisms is available. Laboratory diagnosis includes recovery on routine media and detection on Gram- and Giemsa-stained smears. Natamycin and amphotericin B ocular preparations are used to treat common infections.

Parasites

Parasitic infestation of the conjunctiva is generally rare. Ocular sites are occasionally a secondary complication of systemic parasitic worm infections. Onchocerciasis (river blindness), transmitted by the bite of the blackfly, is a leading cause of blindness in Africa and is in limited areas of South America and the Middle East. Ocular complications result from the discharge of large numbers of microfilariae by the adult female and their subsequent local invasion and tissue damage leading to keratitis from chronic infection. Recovery and diagnosis of ocular involvement depends on observing and removing the larvae (microfilariae) and confirming their presence through histologic staining, isolating the organisms from blood or tissues, or confirming their presence by serologic means. The recommended treatment for onchocerciasis is ivermectin, which kills the larvae and prevents them from causing damage but does not kill the adult worms. Ivermectin will need to be given every 6 months for the life span of the adult worms or as long as there is evidence of infection.

Infections of the eyelids

Blepharitis and conjunctivitis are not mutually exclusive. Conjunctivitis usually presents as blepharoconjunctivitis. Therefore any organism that causes conjunctivitis can affect the eyelids. However, each site has unique organisms and conditions. The skin covering the eyelids is the thinnest in the body. Any organisms capable of initiating skin infections can also cause blepharitis.

Bacteria

S. aureus and the coagulase-negative staphylococci are the bacteria most frequently isolated from the eyelid margins. Blepharitis involving these organisms is a low-grade inflammation associated with functional disease of the seborrheic glands (seborrheic blepharitis). In this mixed infection, dry

(staphylococcal) and greasy (seborrheic) scales are attached to the eyelashes, with various areas of ulcerations that cause the lashes to fall out. Antimicrobial agents are given to treat the staphylococcal disease. Because the scalp, eyebrows, and eyelids are all involved in seborrhiasis, all must be kept clean by using a medicated shampoo.

Four types of glands are located in the lids: the meibomian gland, the glands of Moll and Zeis, and accessory lacrimal glands. Acute infection of the glands of Zeis or Moll with staphylococci results in an external hordeolum (stye). A **stye** is an abscess with pus formation in the lumen of the affected gland. Hot soaks assist in the continuous drainage of the abscess. Erythromycin or tetracycline may be applied topically as supplementary therapy. An internal hordeolum caused by staphylococci is a little larger and affects the meibomian gland. Only rarely does the laboratory receive a request for culture of eyelid specimens. If such a request is received, it is to confirm the presence of staphylococci and determine whether therapy is adequate. Other microbial agents recovered from patients with blepharitis are listed in [Box 41.3](#). *Actinomyces* spp. may spread from the facial skin to the eyelids. *Mycobacterium* spp. that cause ocular infections are listed in [Box 41.1](#).

Viruses

Viral blepharitis can be caused by HSV-1, HSV-2, VZV, poxviruses, or papovaviruses. HSV infection usually occurs during early childhood. Vesicles appear on the eyelid margins and the skin around the eye. The vesicles break open and form crusted secondary lesions, which can then become superinfected by skin organisms. Direct detection with immunofluorescence or immunoperoxidase can be done by scraping the

BOX 41.3 Microorganisms associated with blepharitis

Bacteria

Common isolates

Staphylococcus aureus
Staphylococcus epidermidis and other coagulase-negative staphylococci
 Group A and other β -streptococci
Moraxella lacunata, *Moraxella* spp.

Rare isolates

Bacillus cereus
Haemophilus ducreyi
Clostridium spp.
Actinomyces spp.
Mycobacterium tuberculosis
Mycobacterium leprae

Fungi (rare)

Candida spp.
Cryptococcus neoformans
Blastomyces dermatitidis
 Dermatophytes (*Microsporum*, *Trichophyton*, *Epidermophyton* spp.)

Viruses

Herpes simplex virus types 1 and 2
 Varicella-zoster virus
 Molluscum contagiosum virus
 Vaccinia virus
 Papovavirus

base of a freshly opened vesicle. Vesicular fluids are collected for culture; 95% or more of cultures grow HSV within 72 hours or less.

When the face is involved during episodes of chickenpox (varicella), vesicles may appear on the upper or lower eyelid margins. Molluscum contagiosum is a wartlike lesion of the eyelid margins produced by a poxvirus. The lesion is waxy and pearly white, with an umbilicated center. Expression (squeezing) of the white center to allow blood into the lesion is usually adequate management. Vaccinia infection of the eyelids results from direct inoculation from a smallpox vaccination. Other viruses that produce ocular warts are members of the papovavirus family.

Infections of the cornea

Microbial keratitis is considered a true ocular emergency. Few organisms can invade the intact cornea. If the cornea epithelium is breached by trauma, contact lens insertion and removal, or surgery, organisms can enter and cause infections. Infection begins in the most superficial layer (the epithelium); if unchecked, infection advances through the Bowman zone, stroma, and the Descemet membrane to the endothelium (the innermost layer). Perforation of the Descemet membrane compromises vision and must be treated aggressively with antimicrobials and/or surgical intervention.

In the United States, contact lens use is considered the greatest risk factor for developing microbial keratitis. The incidence of keratitis related to extended-wear contact lenses is approximately 20 per 10,000 people, although the incidence for daily-wear contact lenses is about 1 per 10,000 people. A study in France found that the greatest risk factor for keratitis was using disinfecting solution for more than 3 months (odds ratio 1.94). Additional risk factors for microbial keratitis include trauma and refractive surgery and poor hygiene when handling lenses.

Bacteria

Geographic variations in the causes of bacterial and fungal ulcers are evident in the United States. *P. aeruginosa* is the isolate most frequently recovered from patients with contact

lens-associated keratitis. *S. aureus* is another frequently recovered pathogen (Fig. 41.5). There is also a seasonal distribution of causative agents. One study in Brooklyn, New York, found that in cases occurring in summer, 47.6% of culture-positive ulcers had *P. aeruginosa*. In the remaining seasons, *P. aeruginosa* was found in less than 13% of positive cultures. In this study, 39% of the patients with keratitis wore contact lenses. Fig. 41.6A shows the growth of *P. aeruginosa* from a contact lens. Fig. 41.6B lists trends in the types of bacteria recovered from contact lenses and solutions.

Mycobacterium chelonae, *Mycobacterium abscessus*, and other rapid-growing mycobacteria are being isolated with increasing frequency from patients with keratitis (Fig. 41.7). Risk factors include laser-assisted in situ keratomileusis (LASIK) eye surgery, trauma, and contact lens use. Reservoirs include contaminated instruments and/or soil and water. Less frequently encountered corneal isolates are listed in Box 41.4.

Laboratory diagnosis

Laboratory assistance with diagnosis is mandatory in all cases of suppurative keratitis or keratitis not responding to therapy. Ideal specimens for examination of smears and for culture are corneal scrapings, which are collected by an ophthalmologist. Material should be inoculated directly onto culture plates and slides and sent immediately to the laboratory. Scrapings for stains can provide the health care provider with an early indication of the offending organism and assist in the selection of appropriate therapy. The cornea may also be invaded via metastatic spread from the conjunctiva or systemic lesions; therefore other specimens might be useful in diagnosis.

Case check 41.2

The best specimen for the diagnosis of keratitis is a corneal scraping, as was submitted in the Case in Point. The green mucopurulent discharge is suggestive of *P. aeruginosa* conjunctivitis and/or blepharitis. To reduce the risk of permanent eye damage and vision loss, it is important to begin appropriate therapy immediately. This would involve empiric treatment with a broad-spectrum antimicrobial agent before complete culture results are obtained.

Fig. 41.5 A, Corneal melt caused by bacterial invasion. B, C streaks of *Staphylococcus aureus* from an infected cornea. The enzymes produced by some strains of *S. aureus* and *Pseudomonas aeruginosa* can liquefy the cornea within 48 hours.

A

B

Fig. 41.6 A, Growth of *Pseudomonas aeruginosa* from daily wear (soft) contact lens. The patient had an ulcerative keratitis. The corneal culture also grew *P. aeruginosa*. B, Recent trends in bacteria recovered from contact lenses and solutions.

Fig. 41.7 Colonies of *Mycobacterium fortuitum* growing on infected corneal graft tissue.

BOX 41.4 Isolates

Mycobacterium abscessus
Mycobacterium asiaticum
Mycobacterium avium complex
Mycobacterium chelonae
Mycobacterium fortuitum
Mycobacterium gordonae
Mycobacterium mucogenicum
Mycobacterium nonchromogenicum
Mycobacterium szulgai
Mycobacterium triviale

Mycobacterium tuberculosis and *Mycobacterium leprae* are ocular pathogens and are usually an extension of systemic disease. Isolates are frequently recovered from patients who wear contact lenses, have a history of eye trauma from soil or water, or have undergone refractive surgery.

Treatment

Therapy is often selected on the basis of the results of smear examinations and/or chosen empirically for the most likely pathogen. Management includes topical antimicrobial drops or ointments supplemented with oral or systemic antimicrobials.

Viruses

HSV is a leading cause of infectious blindness and ocular morbidity in the United States and other countries.

Fig. 41.8 Frequency of common keratitis viral isolates in southern Florida. HSV-1, Herpes simplex virus type 1; HSV-2, herpes simplex virus type 2.

Worldwide, approximately 1.5 million new cases of HSV keratitis occur each year, including 40,000 cases of visual impairment or blindness. Keratitis caused by HSV may result from direct inoculation or reactivation of latent virus in the trigeminal ganglion. Most of the ocular lesions are caused by HSV-1, but HSV-2 has been recovered from cases involving infants and adults. Fig. 41.8 shows the frequency of common keratitis viral isolates in cases in southern Florida. Scarring and blindness result from repeated outbreaks and surgical interventions. The lesions caused by these two are indistinguishable.

Laboratory diagnosis includes direct detection using monoclonal antibodies, DNA probes, PCR assays, and/or growth in cell culture. Treatment includes debridement, when possible; topical antivirals; and corneal transplantation. Other viral agents that cause keratitis are listed in Box 41.5.

Fungi

Fungal infections of the cornea are usually associated with opportunistic or saprophytic organisms. More than 70 genera have been documented as causative agents in fungal keratitis. Filamentous organisms, mainly *Fusarium*, *Aspergillus* spp., *Scedosporium apiospermum*, and *Paecilomyces*, are common pathogens in warm climates, whereas *Candida* spp. are common in cooler climates. Patients often have a history of

trauma involving soil or plant material and occurring most frequently in agricultural workers. Other high-risk factors include allergic conjunctivitis, eye surgery, treatment with broad-spectrum antimicrobial agents and corticosteroids, and contact lens use. In 2005 to 2006, the CDC reported an outbreak of at least 130 confirmed cases of *Fusarium* sp. keratitis associated with contaminated contact lens solution. All cases of fungal keratitis must be confirmed by the laboratory. Fungal keratitis agents are listed in Box 41.5.

Samples for culture must be collected from multiple scrapings of the involved, actively advancing edges of the ulcer. Biopsy is sometimes necessary to isolate the fungi. Giemsa and calcofluor white preparations from scrapings can confirm

BOX 41.5 Microorganisms associated with keratitis

Bacteria

Gram-negative isolates

Haemophilus influenzae
Moraxella spp.
Proteus mirabilis
Pseudomonas aeruginosa
Serratia marcescens

Gram-positive isolates

Corynebacterium spp.
Staphylococcus aureus
Staphylococcus epidermidis and other coagulase-negative staphylococci
Streptococcus pneumoniae
 Viridans group streptococci

Uncommon isolates

Nocardia spp.
Capnocytophaga spp.
Cutibacterium acnes
 Mycobacteria other than tubercle bacilli
Acanthamoeba and other free-living amoebae

Viruses

Adenoviruses
 Cytomegalovirus
 Enteroviruses
 Epstein-Barr virus
 Herpes simplex virus types 1 and 2
 Human immunodeficiency virus (tears and stroma)
 Measles virus
 Mumps virus
 Vaccinia virus
 Varicella-zoster virus

Fungi

Acremonium spp.
Alternaria spp.
Aspergillus spp.
Bipolaris
Candida spp. (*Candida parapsilosis* and *Candida tropicalis* most common)
Curvularia spp.
Fusarium spp. (*Fusarium solani* and *Fusarium oxysporum* most common)
Paecilomyces spp.
Phialophora spp.
Scedosporium boydii
Trichosporon beigelii

hyphal elements or budding yeasts. Topical antifungals include natamycin, nystatin, and imidazole. Topical preparations from systemic antifungals like voriconazole and amphotericin B may be used to manage fungal keratitis. Systemic antifungals may be needed for perforated ulcers. Corneal transplantation is often necessary to restore sight.

Parasites

Amoebae

Infection of the cornea by free-living amoebae (e.g., *Acanthamoeba* spp., *Naegleria* spp., and *Vahlkampfia* spp.) is a painful and sight-threatening consequence of injury or exposure to contaminated water, contact lenses, or soil. Wearing contact lenses while swimming in contaminated water or showering is a high risk factor for infection. In addition, topping off new solution with old, and not following proper protocol in handling, disinfecting, and storing contact lenses can lead to biofilm formation by bacteria, such as *P. aeruginosa*. This can provide a nutrient-rich environment for amoebae. *Acanthamoeba* spp. are the most frequent isolates. There have also been reports of contamination of contact lens solution. Amoebic keratitis is often mistaken for viral or fungal keratitis, and a diagnosis of amoebic keratitis is generally made when culture or NAAT results are negative for bacteria, fungi, and viruses. Confocal microscopy of corneal scrapings along with clinical findings had a reported sensitivity of 90.6% and a specificity of 100% for *Acanthamoeba* keratitis.

One method to cultivate the amoeba is to place a few drops of a heavy suspension of *Escherichia coli* or *Enterobacter aerogenes* in the middle of a petri dish containing nonnutrient media of 1.5% Difco agar made with Page's saline. The drop is spread by using a sterile bacteriologic loop. Ocular material is then added to the center of the plate. The bacteria serve as a nutrient source for *Acanthamoeba* spp. The amoebic trophozoites are identified by locating them at the end of the tracts they generate as they ingest the bacteria. Depending on the quality of the scrapings and infectious dose of the organism, *Acanthamoeba* trophozoites may be seen on agar within 48 hours. The polygonal, double-walled cysts may be detected on a direct smear with Giemsa or calcofluor white staining. Trophozoites are much less discernible on smears and are best seen in tracts on the agar (Fig. 41.9).

Another method is to inoculate scrapings into cell cultures. The amoebae cause a generalized destruction of the tissue culture cells. A third method of cultivation is to grow free-living amoebae in broth culture (axenic, free from other living organisms). The presence of *Acanthamoeba* spp. may also be confirmed by using molecular techniques.

Treatment of *Acanthamoeba* keratitis is difficult and includes debridement in early disease. No amoebicidal agents are currently approved. Patients are often treated with a combination of drugs, such as topical propamidine or hexamidine (0.1%) solution with biguanide chlorhexidine (0.02% to 0.2%) or polyhexamethylene biguanide (0.02% to 0.06% solution). Corneal transplantation is often necessary.

Microsporidia

Microsporidial keratitis, seen in immunocompromised patients, such as those with AIDS, is a disease that has appeared recently. Infections have also been seen in immunocompetent

contact lens wearers. Microsporidiosis is usually associated with contact with bees or other insects. The microsporidia are intracellular, spore-forming fungi. Because their morphology resembles protists, they are often discussed with the parasites. In humans, both ocular and nonocular diseases caused by these organisms have been reported. These pathogens are obligate intracellular parasites that infect ocular conjunctivae and corneal tissue. Their size ranges from 1 to 20 μm and is round or spherical (Fig. 41.10). The organism develops in two stages: the schizogenic phase and the sporulation, or sporogenic, phase. There are several pathogens in this group: *Encephalitozoon* spp., *Nosema oculorum*, and *Vittaforma corneae*.

Spores may be detected with hematoxylin and eosin, Gram, Giemsa, acid-fast, or calcofluor white stains. Because of their small size, it takes training and expertise to accurately identify microsporidia in tissue specimens. Some microscopists prefer the tissue Gram stains Brown-Brenn or Brown-Hopps or a silver stain (e.g., Warthin-Starry stain). Electron microscopy is usually required for taxonomic classification. Detection of ocular parasites is based on the following: (1) observing the organism, (2) confirming the presence of the organism with histologic or other staining methods; and (3) isolating the organism from blood, tissues, or body fluids. No uniform treatment is available, and treatment depends on the organism, the patient's underlying conditions (such as HIV/AIDS)

Fig. 41.9 Tracts of *Acanthamoeba* trophozoites. The meandering trophozoites are at the end of the tracts. The large clusters of organisms contain trophozoites and cysts (unstained).

Fig. 41.10 Gram-stained smear revealing the oval cyst of *Microsporidia* spp. Organisms can also be detected with Giemsa, acid-fast, and calcofluor white stains.

and availability of an effective anti-infective. In addition, if there is disseminated disease, an extended course of oral albendazole is also recommended.

Infections of the sclera and episclera

The sclera is composed of tough collagen fibers, and few organisms can penetrate this strong protective coat. Infections are protracted, painful, and quite destructive. **Scleritis** is usually a local manifestation of systemic connective tissue disease (e.g., rheumatoid arthritis, systemic lupus erythematosus) or the result of contiguous spread of infection from adjacent ocular tissues. The presentation may be acute (pyogenic) or chronic (granulomatous). The episclera is the outermost layer of the sclera. Inflammation of this tissue is termed *episcleritis*. Episcleritis is more common than scleritis and has an undetermined cause in 70% of cases.

Laboratory diagnosis includes collection of tissue or discharge from the site and plating on routine and special media for common and infrequent isolates. Treatment is dependent on the organisms. Surgical intervention may be necessary to retard progression.

Infections of the orbit

Preseptal cellulitis is infection of the eyelids and soft tissues surrounding the orbit. It is a medical emergency in children. Infection can lead to blindness or death if not treated immediately and aggressively in all age groups. Predisposing factors include trauma, lower respiratory tract infections, impetigo, and herpetic diseases. *S. aureus*, *H. influenzae*, *S. pneumoniae*, and *S. pyogenes* are recovered in most preseptal cellulitis cases. Laboratory testing includes examination of direct Gram-stained smears and aerobic and anaerobic cultures. Broad-spectrum coverage for *S. aureus*, *H. influenzae*, *S. pneumoniae*, and *S. pyogenes*, which constitute 95% of the microorganisms recovered from cases of preseptal cellulitis, is recommended.

Infections of the orbit and associated structures may have a devastating effect on vision and ocular structural integrity. The close proximity of the orbit and related tissues to the paranasal sinuses, the absence of an effective drainage system from this sequestered area, and the unique structure of the eyelids predispose this area to invasion by various microorganisms. Infectious agents can gain entry into the orbital tissue through trauma or injury to the eyelids or orbit resulting from surgery, infections of the eyelids and adjacent skin, upper respiratory tract infections, and dental caries. Parasites may also invade the orbital tissue and cause considerable destruction. Orbital infections can also be extensions of bacterial or fungal sinus infections. Any organisms that initiate sinusitis can also cause **orbital cellulitis**. Various anaerobic organisms are isolated from samples from patients with orbital cellulitis associated with longstanding chronic sinusitis. Most of these infections are caused by bacteria, but saprophytic fungi may also be involved. Usually, both aerobic and anaerobic bacteria are isolated from these infections.

Chronic orbital cellulitis may be caused by *Mycobacterium* spp., *Nocardia* spp., and *Actinomyces* spp. Bacterial infections associated with orbital implants or prostheses present increasing threats to vision. The organisms recovered include

M. chelonae, *Nocardia* spp., *S. epidermidis*, *Capnocytophaga* spp., *Candida parapsilosis*, and *C. acnes*.

Trichinosis, caused by the nematode *Trichinella spiralis*, can invade the extraocular muscles and result in periorbital edema and pain on eye movement. It is the ophthalmologist who usually makes the diagnosis of trichinosis because invasion of the ocular muscles is generally one of the first signs of this disease. Other parasitic infections are rare.

Aspirates for smears and cultures are collected and placed onto slides by an ophthalmologist and sent immediately to the laboratory. Stains from tissues and/or aspirates can afford the health care provider an early indication of the offending organism and assist in the selection of appropriate therapy. Systemic therapy should be instituted as soon as appropriate culture samples (conjunctiva, nasal, and blood) are collected and should provide coverage for aerobic and anaerobic pathogens.

Infections of the lacrimal apparatus

The lacrimal glands, accessory glands, puncta, canaliculi, tear sac, and nasolacrimal duct together are known as the *lacrimal apparatus*. Disorders and infections of the lacrimal apparatus are caused by blockage or underproduction or overproduction of tears. Inflammation of the lacrimal or tear sac—**dacryocystitis**—is the most common infection of the lacrimal apparatus. Infections are usually seen in infants and are associated with obstruction of the nasolacrimal sac. Infections are characterized by tearing and discharge from the eye, an inflamed sac, and pain (Fig. 41.11). Any organism that colonizes the nasolacrimal sac could be responsible for lacrimal sac infections (Box 41.6). *C. trachomatis* may cause a recurrent, chronic inflammation of the tear sac. *Aspergillus* spp., *Candida* spp., and *Actinomyces* spp. may also be recovered.

Dacryoadenitis, inflammation of the main lacrimal gland, may be infectious or noninfectious. Organisms are seeded into the gland via the bloodstream. Blunt trauma also predisposes the gland to infection. Common bacterial isolates include *N. gonorrhoeae*, *S. aureus*, and *Streptococcus* spp. Chronic bacterial infections of the gland involve tuberculosis, syphilis, or leprosy (Hansen disease). Mucormycosis and aspergillosis can result from contiguous spread from infections of the orbit. Mumps and infectious mononucleosis are the common viral

Fig. 41.11 Dacryocystitis (infection of the lacrimal sac) of the left eye (arrow) in a young patient. (From Zitelli, B. J., & Davis, H. W. (2008). *Atlas of pediatric physical diagnosis* (5th ed.). Philadelphia: Mosby.)

infections associated with the lacrimal gland. Subclinical or inapparent infections have occurred in patients with HSV, VZV, CMV, coxsackievirus A, and echoviruses. Other viruses implicated in lacrimal gland infections include measles and influenza viruses.

Canaliculitis, a disease found exclusively in adults, is a low-grade inflammation that affects the lower canaliculus more than the upper canaliculus. Purulent, cheesy material may be expressed from the lumen. The causative agents are diverse and include bacteria, fungi, and viruses. Bacterial infections consist of mixed aerobic and anaerobic species; *S. aureus* and streptococci are among the aerobes recovered (see Box 41.6). Aerobic isolates include gram-negative bacilli and *C. trachomatis*. The predominant anaerobic pathogens recovered include *Actinomyces israelii*, *Propionibacterium propionicus*, *C. acnes*, *Nocardia*, and *Fusobacterium*. Fungal isolates include *C. albicans* and *Aspergillus* spp. HSV and VZV may also inflame the canaliculi.

Materials for microbiological evaluation include drainage material, pus, and exudate. Direct smears and cultures for bacteria and fungi should be prepared from these materials. The causative agents (e.g., *Actinomyces* spp.) including fungal hyphae are often seen in large numbers. Infections with mixed organisms are also evident. Media should be inoculated to recover aerobic and anaerobic bacteria and fungi.

BOX 41.6 Microorganisms associated with lacrimal apparatus infections

Bacteria

Actinomyces israelii
Capnocytophaga spp.
Chlamydia trachomatis
Fusobacterium spp.
Haemophilus influenzae
Mycobacterium tuberculosis
Mycobacterium leprae
Pseudomonas aeruginosa
Proteus mirabilis
Cutibacterium acnes
Staphylococcus aureus
Streptococcus pneumoniae
Streptococcus pyogenes

Viruses

Coxsackie virus A
 Cytomegalovirus
 Echoviruses
 Epstein-Barr virus
 Herpes simplex virus types 1 and 2
 Influenza virus
 Measles virus
 Varicella-zoster virus

Fungi

Aspergillus spp.
Candida albicans
Rhizopus spp.
Mucor spp.

Parasites

Cysticercus cellulosae
Onchocerca volvulus

Infections of the intraocular chambers

Infectious **endophthalmitis**, inflammation of intraocular tissues or cavities, is a catastrophic complication of surgery, contiguous spread of infection from infected tissues, use of contaminated medications, or penetrating ocular trauma. Endophthalmitis may also be caused by instillation of contaminated eye drops and implantation of contaminated biomaterials. It is the most serious and sight-threatening of all ocular infections. Any organism that gains entry into the inner chambers of the eye can result in disease. The causative agents include bacteria, viruses, fungi, and parasites (Box 41.7).

Bacteria

S. epidermidis and other coagulase-negative staphylococci are the most frequent pathogens. Contamination of intraocular chambers and/or the intraocular lens with conjunctival microbiota is the common reservoir for these infections. Bacterial endophthalmitis is often associated with infected biomaterials (e.g., intraocular lens, scleral buckles) following cataract and/or retinal surgery. *Bacillus cereus* and other *Bacillus* spp. are the organisms most frequently isolated from patients with endophthalmitis resulting from traumatic injury. The onset of

symptoms is sudden, and the course is fulminant. Release of necrotizing enzymes can result in loss of the eye within 48 hours. A high index of suspicion followed by aggressive therapy is required to ensure that patients retain useful vision.

Fungi

Mycotic endophthalmitis is mostly an extension of keratitis. However, it can also result from hematogenous spread from a remote focus and from implantation of contaminated intraocular lenses. The most frequent isolates are *C. albicans* and other *Candida* spp. Saprophytes that infect the cornea may extend into the intraocular cavities. The filamentous species recovered include *Aspergillus* spp., *Fusarium solani*, *Paecilomyces* spp., *Curvularia* spp., and *S. schenckii*. Other reported species recovered in cases of endophthalmitis include *Monosporium apiospermum*, *Cephalosporium* spp., *Volutella* spp., *C. immitis*, *H. capsulatum*, *C. neoformans*, and *B. dermatitidis*. *Pneumocystis jirovecii* may be isolated from patients with human immunodeficiency virus (HIV) infection. Blood cultures growing fungus warrant an ophthalmologic examination to evaluate for evidence of fungal endophthalmitis and/or retinitis.

Parasites

Intraocular parasites usually affect the retina or choroid or are transient invaders from adjacent ocular structures. *Onchocerca* spp., *Toxocara* spp., and *Toxoplasma gondii* are the most frequent intraocular pathogens.

BOX 41.7 Microorganisms associated with endophthalmitis

Bacteria

Achromobacter xylosoxidans
Actinomyces spp.
Bacillus spp.
Capnocytophaga spp.
 Enterobacterales
Enterococcus faecalis
Haemophilus influenzae
Moraxella spp.
Mycobacterium chelonae
Cutibacterium acnes
Proteus mirabilis
Pseudomonas aeruginosa
Serratia marcescens
Staphylococcus aureus
Staphylococcus epidermidis and other coagulase-negative staphylococci
 Viridans group streptococci

Viruses

Cytomegalovirus
 Enteroviruses
 Herpes simplex virus types 1 and 2
 Varicella-zoster virus

Fungi

Aspergillus spp.
Candida spp. (*Candida albicans* most common)
Cryptococcus neoformans
Curvularia spp.
Fusarium spp.
Paecilomyces spp.

Parasites

Onchocerca volvulus
Toxoplasma gondii
Toxocara spp.

Laboratory diagnosis

Rapid recovery and identification of the invading organism complemented by early, specific, and aggressive therapy are mandatory to prevent loss of useful vision and preserve internal ocular structures. Specimens include aspirated anterior chamber or vitreous fluids (usually <5 mL) and washings from the flushing out of vitreous chambers (usually >10 mL). Because the volumes are generally small, intraocular fluids are plated directly onto selected media. Chocolate agar should be used, and other media are selected for other pathogens after consultation with the ophthalmologist. Drops are placed on slides for Gram, Giemsa, or calcofluor white stain. Vitreous washings are filtered through a 0.45- μ m Teflon filter, the filter is sectioned, and sections are placed on selected media (Fig. 41.12).

Retinitis

Inflammation of the retina is often associated with viral infection, such as HSV, VZV, and CMV. Fungi such as *Candida* spp. also can cause infection of the retina. No ophthalmic samples are acquired. This is diagnosed by ophthalmologic examination with possible blood culture.

Biofilm-centered ocular infections

Microorganisms in biofilms (see Chapter 31) are causative agents in a variety of ocular infections (Table 41.2). These include contact lens-associated and crystalline keratitis, late-onset postoperative endophthalmitis, and orbital implant infections. Biomaterial-centered infections have also been

Fig. 41.12 **A**, Section from a filter used to concentrate vitreous fluids. Once the fluids have been filtered, the 0.45- μ m filter is sectioned, and sections are placed on selected media. **B**, *Curvularia* spp. from intraocular fluids on a 0.45- μ m filter section. **C**, *Burkholderia cepacia* on a filter from a vitrectomy specimen.

Table 41.2 Biofilm-associated ocular disease

Clinical disease	Biomaterial and/or biofilm origin	Recovered or common organisms
Contact lens–associated keratitis	Hydrogel and silicone (soft) contact lens PMMA (hard) contact lens	<i>Pseudomonas aeruginosa</i> <i>Staphylococcus aureus</i> Coagulase-negative staphylococci
Crystalline keratitis	Damaged tissue	Viridans group streptococci <i>Candida</i> spp.
Diffuse lamellar keratitis	Damaged tissue	Endotoxins, microbial products released from biofilms
Radial keratotomy	Damaged ocular tissue	Viridans group streptococci
Intracorneal rings	Damaged tissue implant	<i>Serratia marcescens</i> <i>Pseudomonas aeruginosa</i>
Endophthalmitis	Intraocular lenses	Coagulase-negative staphylococci (<i>Staphylococcus epidermidis</i> —most frequent) <i>Cutibacterium acnes</i> <i>Candida albicans</i>
Orbital implant infections	Implant Orbital tissues	<i>S. aureus</i>
Glaucoma drainage	Implant Damaged tissue	<i>S. aureus</i> <i>Mycobacterium</i> spp.
Punctual plugs	Implant Damaged tissue	<i>S. epidermidis</i>
Lacrimal plugs	Implant Damaged tissue	<i>Mycobacterium chelonae</i> <i>S. aureus</i>

PMMA, Polymethylmethacrylate.

documented for ocular keratoprosthesis, glaucoma shunts, and ocular sutures. Biofilms can form on a variety of ocular biomaterials and/or on damaged ocular tissues. The ocular biomaterials most frequently predisposed to biofilm formation include contact lenses, intraocular lenses, and corneal and orbital implants. Common pathogens include coagulase-negative staphylococci, *S. aureus*, *C. acnes*, *C. albicans*, and *P. aeruginosa* (Fig. 41.13). Biofilm-centered ocular infections are recalcitrant to antimicrobial therapy, and the sequestered biofilm-encased organisms are protected against the host's humoral and cellular immunity. Complications include chronic infections, decreased vision, and blindness. Removal of the biomaterial is often necessary to resolve the infection or inflammation.

Laboratory diagnosis of ocular infections

Specimen collection

The keys to proper collection of ocular specimens are similar to those for any other microbiological specimen. Materials or

Fig. 41.13 Fungal (yeast) biofilm on a contact lens. The culture grew *Candida albicans*.

scrapings for cultures should be collected as soon as possible after the onset of infection (24 to 48 hours for bacteria and 3 to 7 days for viruses) and before the instillation of antimicrobials or steroids. The sample must be collected from the actual site of the infection; for example, conjunctival and eyelid cultures are inadequate to assess corneal involvement. All ocular fluids, tissues, sponges, and other surgical materials must be submitted in sterile, leakproof containers that are properly labeled.

The ophthalmologist must communicate with the laboratory scientists performing the microbiological evaluation of the specimen to ensure isolation of ocular pathogens. It should be noted whether the patient is a contact lens wearer. For best results, ocular materials must be inoculated directly onto appropriate media. Scant recovery is the norm when transport swabs are submitted for recovery of ocular pathogens. The type of swab used can further reduce organism recovery. Cotton-tipped swabs inhibit the growth of some bacteria and HSV because of the fatty acids released during sterilization. Dacron or calcium alginate swabs may be used to collect ocular samples. However, calcium alginate swabs may inactivate some viral pathogens.

Materials expressed from areas such as canaliculi are preferred to rule out infection (Fig. 41.14). Materials are inoculated directly onto media. Smears are also prepared from the materials. Collection by direct aspiration or scraping is performed by the ophthalmologist. Media to recover aerobic and anaerobic organisms must be included. Vitreous washings (with a volume >10 mL) may be injected into blood culture bottles or viral transport media or sent to the laboratory for concentration through a 0.22- or 0.45- μ m filter (see Fig. 41.12). Biopsy tissue must be minced or ground. Media to recover aerobic and anaerobic bacteria, fungi, and mycobacteria should be inoculated. If amebae are suspected, two nonnutrient agar plates should be included.

Direct microscopic examination

Conjunctival and corneal scrapings, intraocular fluids, and aspirates are collected by an ophthalmologist using a Kimura spatula, blade, or sterile swab. Scrapings and fluid aspirates from the involved ocular site complemented with the appropriate stains, can give the health care provider circumstantial and definitive information concerning the identity of the invading organisms. Table 41.3 provides a summary of stains

Fig. 41.14 A, Concretions being expressed from canaliculi. B, Smashed and stained concretions, revealing gram-positive, slender, branching rods (*Actinomyces israelii*).

that are routinely used in ocular microbiology and appropriate applications of each procedure. Gram and Giemsa stains (Fig. 41.15) should be used for all suspected cases of bacterial conjunctivitis, keratitis, and endophthalmitis. Calcofluor white stain should be added to rule out fungal or parasitic disease. A fluorescent or acid-fast stain is used to detect the presence of acid-fast organisms. In addition, impression

cytology using 0.45- μ m Teflon-coated membrane filters to collect conjunctival and corneal tissue may increase bacterial, fungal, viral, and protozoal detection by as much as 50%. The advantage of this technique is that cells remain intact, with characteristic morphology and microbial infestation and invasion (Fig. 41.16).

Culture and identification

Most bacterial and fungal ocular isolates may be recovered on chocolate and blood agar when incubated under the proper conditions of 35° C and 5% to 10% carbon dioxide. Additional plates should be incubated anaerobically. Table 41.4 shows a general plating guide that may be followed to recover typical agents of ocular infections. The addition of thioglycollate broth, Thayer-Martin agar (for the pathogenic *Neisseria*), Sabouraud dextrose agar with gentamicin (Fig. 41.17), Löwenstein-Jensen slants, and non-nutrient agar plates allows the recovery of most pathogens involved in ocular disease. All thioglycollate tubes are held for 10 days or for 21 days if there is suspicion of *Actinomyces* spp. or *C. acnes*. The fungi that traditional mycology media aim to inhibit (saprophytes) are the agents usually recovered in mycotic ocular disease (e.g., *Fusarium* spp., *Paecilomyces* spp., *Aspergillus* spp., *Penicillium* spp.). Therefore media with cycloheximide should be avoided. Very little clinical material is often available; media should be inoculated at the bedside. Vitreous humor should be centrifuged and the sediment used for media and smears.

Interpretation of growth from ocular samples is based on the same sound microbiological criteria used in general hospital microbiology laboratories. Quantitation of growth is particularly important. Samples from patients receiving antimicrobial agents, steroids, or other medications may have reduced microbial growth, which should be considered when evaluating the culture. Special considerations are involved in corneal and intraocular fluid cultures. Traditionally, corneal scrapings are inoculated in a C-streak fashion (Fig. 41.18). Each row of C streaks represents a separate scraping of a corneal ulcer. The dilution effect is from left to right. Generally, more colonies of bacteria or fungi appear on the first C streaks of each row. Each successive C streak progresses from the

Organism	Gram	Giemsa	IF	IC	CFW
Bacteria	+	+			
Fungi ^a	+	+			+
Viruses		+	+	+	
Chlamydia		+	+	+	
Parasites	+	+		+	+

^aThe tissue Gram stains Brown-Brenn and Brown-Hopps or the Warthin-Starry silver stain are preferred for microsporidia.

CFW, Calcofluor white stain (used to detect fungi or parasites in ocular tissue); IC, impression cytology (collected cells remain intact, and test can track disease progress); IF, immunofluorescent stains (monoclonal antibodies for chlamydia, herpes simplex virus, adenovirus, enterovirus, varicella-zoster virus, and cytomegalovirus).

Fig. 41.15 Giemsa-stained smear of conjunctival epithelial cells with chlamydial inclusions (arrow). The Giemsa stain also provides information on the types and numbers of inflammatory cells and the condition of the epithelial cells.

Fig. 41.16 **A**, Cornea stained with rose bengal stain to outline a dendrite infected with herpes simplex virus (HSV). HSV is the virus most often isolated from corneal dendritic infections. **B**, Dendrite on a membrane filter collected by impression cytology. The filter was stained with a monoclonal antibody against HSV-1. Almost all cells of the dendrite fluoresced when stained. The uninfected cells do not stain and appear red.

*Additional procedures include acid-fast bacillus stains, DNA probes, <i>Limulus</i> lysate, and filtration. CMV, Cytomegalovirus; CoNS, coagulase-negative staphylococci; HSV, herpes simplex virus; MOTT, mycobacteria other than tubercle bacilli; NAAT, nucleic acid amplification test; VZV, varicella-zoster virus.														

^aAdditional procedures include acid-fast bacillus stains, DNA probes, *Limulus* lysate, and filtration.

CMV, Cytomegalovirus; CoNS, coagulase-negative staphylococci; HSV, herpes simplex virus; MOTT, mycobacteria other than tubercle bacilli; NAAT, nucleic acid amplification test; VZV, varicella-zoster virus.

Fig. 41.17 Sabouraud agar plate with mold and yeast. The patient had a mixed fungal keratitis. *Top*, The superficial layer of the cornea was infected with a mold (*Fusarium oxysporum*). *Bottom*, The deeper layers were infected with a yeast (*Candida albicans*).

superficial to deep layers of the cornea. The greater the number of corneal streaks with growth, the more involved and serious is the infection.

Any growth from intraocular fluids appearing on the inoculation sites or filter should be assessed and reported. The health care provider correlates the organism's pathology with the patient's clinical picture and diagnosis. Coagulase-negative staphylococci, which are the most common isolates and which are normally considered contaminants, are the ones most frequently involved in microbial intraocular infections (Fig. 41.19). Staining, impression cytology, and tissue culture are routinely used to confirm ocular chlamydial and viral pathogens.

Molecular techniques

Direct antigen detection and NAATs often provide the most rapid and accurate identification, especially in confirming clinical diagnosis for difficult or unusual ocular pathogens. These methods may be ideal for detecting microbes in ocular samples because of the small volume. Molecular techniques have been used to detect *Chlamydia*, herpesviruses, and *Toxoplasma*.

Fig. 41.18 **A**, Contact lens and lens solution on 5% sheep blood agar surrounded by growth of *Pseudomonas aeruginosa*. **B**, C streaks growing pigmented and nonpigmented *Serratia marcescens*. **C**, Corneal scrapings. Note that each row of C streaks represents a separate corneal scraping.

Fig. 41.19 *Staphylococcus epidermidis* recovered from vitreous fluids (drops) on a blood agar plate. Samples may be inoculated onto a chocolate or blood agar plate and allowed to dry or may be streaked as for a routine microbiology specimen.

BOX 41.8 Microbes recovered from contaminated ocular medications

Acanthamoeba spp.
Alcaligenes spp.
Aspergillus spp.
Candida spp.
Citrobacter freundii
 Coagulase-negative staphylococci
Enterobacter cloacae
Klebsiella spp.
Micrococcus spp.
Morganella morganii
Mycobacterium chelonae
 Nonglucose-fermenting gram-negative rods
Ochrobactrum anthropi
Proteus mirabilis
Pseudomonas aeruginosa and other *Pseudomonas* spp.
Serratia spp.
Staphylococcus aureus
Stenotrophomonas maltophilia
Mucor
Rhizopus

BOX 41.9 Microorganisms recovered from contact lenses, contact lens solutions, and contact lens cases

Acanthamoeba spp.
Achromobacter spp.
Acinetobacter baumannii complex
Aeromonas spp.
Agrobacterium tumefaciens
Alcaligenes spp.
Bacillus spp.
Brevundimonas vesicularis
Burkholderia cepacia
Candida spp.
Chryseobacterium spp.
Citrobacter spp.
Comamonas spp.
Enterobacter spp.
Escherichia coli, *Escherichia hermannii*
Flavimonas spp.
Flavobacterium spp.
Fusarium spp.
Gemella spp.
Haemophilus spp.
Klebsiella spp.
Mycobacterium spp.
Neisseria spp.
Ochrobactrum anthropi
Paecilomyces spp.
Propionibacterium spp.
Proteus spp.
Pseudomonas aeruginosa and other *Pseudomonas* spp.
Serratia spp.
Staphylococcus aureus
Staphylococcus epidermidis and other coagulase-negative staphylococci
Stenotrophomonas maltophilia
Streptococcus pneumoniae
Trichoderma spp.
Vahlkampfi and other free-living amoebae
 Viridans group streptococci

Special culture techniques

Contaminated ocular medications

Ophthalmic drops (e.g., antimicrobials, analgesics) are easily contaminated when improperly handled by patients or ophthalmic clinic personnel. Inappropriate handling can contribute to ongoing ocular disorders and initiation of new infections. Even though most ocular medications are prepared with preservatives to inhibit the growth of microorganisms, once the preservative's threshold has been breached, microbes survive, multiply, and are dispensed with the next drop of medication. Medications should be collected from patients with conjunctivitis, keratitis, or endophthalmitis and sent to the laboratory for culture. The medications that are usually contaminated and associated with concurrent patient infection include steroids, beta blockers, antiglaucoma drugs, antimicrobials, and artificial tears. [Box 41.8](#) lists the microbes recovered from contaminated ocular medications.

Contact lenses and solutions

As mentioned previously, contact lenses are major risk factors for microbial keratitis. Keratitis associated with contact lenses (soft, daily wear, extended wear, or disposable) is being reported with increasing frequency. Sources include poor hygiene with handling and maintenance of contact lenses and contact lens solutions and cases. [Box 41.9](#) lists microorganisms recovered from these sites. Contamination of soft contact lenses is usually caused by failure to follow the manufacturer's recommended procedures or by poor hygiene. Soft lenses contain a large percentage of water, allowing pathogens to survive and multiply. Organisms form and attach to biofilms on the contact lens case, contact lenses, or tissue. Placement of the lenses on the cornea delivers a high microbial load and facilitates attachment and entrance into the cornea. The cornea stroma serves as an excellent medium for microbial proliferation and spread. Wearers of hard contact lenses are less susceptible to infection from microbial contamination, which might be related to the type of biomaterials used to make this type of lens.

Cornea storage media and tissue culture

Replacement of diseased or opacified corneas is a common operation performed by ophthalmic surgeons. The new corneal tissue is obtained from donors within 24 hours of death and is preserved in McCarey and Kaufman medium or Dexsol medium. After surgery, the container with the medium and remaining corneal rim is sent to the laboratory for culture. Bacteriologic evaluation of the donor tissue is paramount in reducing the transmission of host-carried disease to the recipient. Viral studies of corneal transplantation tissue have been limited.

Gram-positive organisms, including coagulase-negative staphylococci and *C. acnes*, are the most frequently isolated organisms, but gram-negative organisms and fungi may also be recovered from these media. The actual correlation between isolates and resultant disease is less than 1%. All positive cultures should be reported directly to the surgeon and a final report sent to the eye bank and the health care provider.

POINTS TO REMEMBER

- The external ocular surface is constantly challenged by microbes.
- Ocular infections may be mild or sight-threatening.
- Surface defenses and an intact cornea and globe prevent invasion by most microorganisms.
- Any organism gaining entry to the eye can establish infection.
- Inflammatory response can damage ocular structures.
- Contact lens wear is considered the greatest risk factor for developing microbial keratitis.
- *P. aeruginosa*, *S. aureus*, coagulase-negative staphylococci, *H. influenzae*, and *S. pneumoniae* are bacteria commonly associated with eye infections.
- Infections of the cornea and intraocular structures are medical emergencies.

LEARNING ASSESSMENT QUESTIONS

1. What is the most common gram-positive ocular pathogen?
 - a. *Cutibacterium acnes*
 - b. *Staphylococcus aureus*
 - c. *Corynebacterium* spp.
 - d. Coagulase-negative staphylococci
2. Media for the isolation of fungal pathogens from ocular specimens should not contain which component?
 - a. Gentamicin
 - b. Penicillin
 - c. Cycloheximide
 - d. Streptomycin
3. Which uncommon pathogen found in water, is associated with contact lens use, and can invade corneal tissue?
 - a. *Haemophilus influenzae*
 - b. *Penicillium* spp.
 - c. *Fusarium* spp.
 - d. *Acanthamoeba*
4. Which group of viruses is most frequently involved in ocular disease?
 - a. Herpesviruses
 - b. Adenoviruses
 - c. Enteroviruses
 - d. Poxviruses
5. Nonnutrient agar inoculated with *Escherichia coli* is used to recover which organism from ocular specimens?
 - a. Microsporidia
 - b. *Chlamydia*
 - c. *Fusarium* spp.
 - d. *Acanthamoeba*
6. Requests for culture from which ocular site are received most often? Which organisms are most likely to be recovered?
7. Which stains are used commonly on smears to identify ocular pathogens?
8. What is the most common route of administration for the antimicrobial treatment of uncomplicated conjunctivitis?
9. Which three infectious agents cause sexually transmitted diseases that can also affect the eye?
10. Which procedure is of the most value when performing bacterial cultures to diagnose conjunctivitis?
11. Why are contact lenses a risk for eye infection, and how can this be reduced?
12. Bacteria that cause keratitis associated with contact lenses often initiate infection through which of the following?
 - a. Biofilm formation
 - b. Microbial growth in the contact lens
 - c. Attachment of bacteria to the lens
 - d. Contamination of the lens fluid
13. A patient visits her health care provider because of a blood-red right eye that appears infected. She recently bought a new pair of contact lenses to change the color of her eyes. The health care provider orders bacterial, fungal, and viral cultures, all of which are negative. What is the most probable cause of this infection?
 - a. *Naegleria* spp.
 - b. *Acanthamoeba* spp.
 - c. *Entamoeba* spp.
 - d. *Trichinella* spp.
14. Which condition is considered a true ocular emergency?
 - a. Conjunctivitis
 - b. Blepharitis
 - c. Microbial keratitis
 - d. Scleritis
15. Which parasite is responsible for causing a form of blindness in West Africa?
 - a. *Loa loa*
 - b. *Brugia malayi*
 - c. *Onchocerca volvulus*
 - d. *Wuchereria bancrofti*

Answers to learning assessment questions

Chapter 1

1. The Gram stain must be repeated because the *Escherichia coli* quality control slide gave a false gram-positive reaction. Because of this quality control result, the smear made from the clinical sample could not be accurately interpreted.
2. The most likely cause of the false gram-positive result for *E. coli* was insufficient decolorization time. Crystal violet, the primary stain, was not removed from the bacterial cells.
3. Pili, made up of pilin protein, aid in bacterial attachment to solid surfaces such as mucous membranes. Flagella, consisting of flagellin protein, are responsible for motility.
4. Capsules help microorganisms resist phagocytosis. Phagocytic cells are less able to bind to the capsular polysaccharide than they are to surface proteins. In addition, capsules hide antigens on the surface of bacteria, preventing them from interacting with antibodies produced by an animal in response to an infection.
5. LPS is also known as *endotoxin*. This molecule is toxic to animals, inducing nonspecific effects such as fever, inflammation, hypotension, and shock. LPS contains three regions: an antigenic O-specific polysaccharide, a core polysaccharide, and an inner lipid A. The lipid A moiety is responsible for producing fever and shock conditions in patients infected with gram-negative bacteria.
6. c
7. a
8. b
9. Older bacterial cells are decolorized more easily than younger cells because as cells age, their cell walls become “leaky” and allow molecules to pass more readily out of the cell. In the Gram stain, the crystal violet-iodine complex is more readily lost during the decolorization step.
10. Bacterial spores have a thick protein coat that makes them highly resistant to chemical agents, temperature changes, dehydration, ultraviolet and gamma radiation, and desiccation. They are also metabolically inactive and can therefore survive periods of starvation for years.
11. The three ways in which genetic material may be transferred from one bacterium to another are transformation, transduction, and conjugation. Transformation is the uptake and incorporation of naked or free DNA into a bacterial cell. Transduction is the transfer of bacterial genes by a bacteriophage from one cell to another. Conjugation is the transfer of genetic material from a donor bacterial strain to a recipient strain. Conjugation requires close contact between the two cells.
12. 3' TTACGGACAAC 5'
5' AATGCCTGTTG 3'
13. Uracil
14. During lysogeny, phage DNA is inserted into the bacterial genome, but virus particles are not produced. When the bacterial cell replicates, the viral genome is copied along with the bacterial chromosome. During the lytic cycle, bacteriophages are produced until the bacterial cell dies and is lysed.

9. a
10. b
11. Resident microbiota are organisms that occupy a specific body site for a long time (months to years). Transient biota are those microorganisms that inhabit a site for a short time, or temporarily.
12. The carrier is a host, often asymptomatic, of an infection who can transmit the infecting organism or virus to a susceptible individual.
13. The nutritional status of the site, pH, oxidation-reduction potential, and presence and interference of already established organisms all determine the composition of indigenous biota.
14. The resident microbiota helps: (1) prime the host immune system; (2) produce substances toxic to more pathogenic species; and (3) decrease the numbers of pathogenic organisms by competing for nutrients.
15. Virulence factors produced by *Clostridioides difficile* include toxins A and B. Toxin A acts as an enterotoxin; toxin B acts as a cytotoxin.
16. True pathogens are organisms that cause disease in susceptible hosts a high percentage of the time. An opportunistic pathogen is an organism that can be a member of the indigenous biota of the host. When the host immune system is compromised or changed, the organism takes the opportunity to cause disease.
17. Exotoxins are extracellular substances produced by an organism containing a toxin gene often encoded by phages, plasmids, or transposons. Toxins generally have a specific activity. Endotoxins compose the lipopolysaccharide component of the cell wall of gram-negative bacteria. The toxicity is caused by the lipid A portion of lipopolysaccharide.
18. The following table compares the cells and soluble mediators involved in the innate immune response, the adaptive humoral immune response, and the cellular immune response.

	Cells	Soluble Mediators
Innate immune response	Macrophages Natural killer cells Neutrophils	Complement Cytokines
Humoral immune response	T-helper cells B cells	Antibodies
Cellular immune response	Cytotoxic T cells Helper T cells Macrophages Natural killer cells	Lymphokines

19. The major immune response against extracellular bacteria is antibodies binding and inducing complement-mediated lysis and phagocytosis. The major immune response against intracellular bacteria is cell-mediated immunity, in which TH1 cells activate macrophages to phagocytose and destroy infected cells. The major immune response against viruses is cytotoxic T cells and natural killer cells that target virus-infected cells. Antibodies are only effective in preventing viruses from attaching to and entering host cells.

20. The following are the steps involved in phagocytosis and how microorganisms can evade each step:
 - Contact between the phagocytic cell and the microorganism. Organisms can evade this step by preventing opsonization with antibody and complement and by masking its antigens with a capsule.
 - Formation of the phagosome. The phagocytic cell extends pseudopodia around the microorganism. The microorganism is contained with a membrane (phagosome).
 - Fusion of the phagosome with lysosomes to form a phagolysosome. Organisms can evade this step by leaving the phagosome and residing in the cytoplasm or preventing fusion of the phagosome and lysosomes.
 - Digestion of the organism. Some organisms secrete enzymes such as catalase and superoxide dismutase that break down the oxygen-reactive intermediates that are present to kill and digest the organism. The production of these enzymes makes the organism resistant to digestion. Only a few bacteria can survive inside phagolysosomes.

10. d

Chapter 4

1. Sterilization is a chemical or physical process resulting in the destruction of all living organisms. Disinfection can be either a physical or chemical method that reduces the number of viable cells.
2. Disinfectants are frequently used in hospitals, dental surgery centers, kitchens, and bathrooms to kill infectious organisms on inanimate objects. They are used after cleaning for surfaces that have visible blood or drainage from infected skin. They are also used to clean surfaces such as toilets, sinks, floors, drains, doorknobs, and countertops. Disinfectants aid in maintaining a clean environment to help prevent the spread of bacteria that may cause infections. Antiseptics are used in handwashing such as before a surgical procedure or contact with those who are at high risk of infection, such as newborns. Antiseptics destroy and inhibit the growth of microorganisms on living tissues (e.g., the skin or mucous membranes). They are not as strong as disinfectants, so they should not be used to clean objects and surfaces.

3. Physical methods involve heat (e.g., boiling water, autoclaving, pasteurization, dry heat), radiation (e.g., ionizing and nonionizing), and filtration (e.g., liquid and air). Chemical methods involve both disinfectants and antiseptics. They include chemicals such as alcohols, aldehydes (e.g., formaldehyde and glutaraldehyde), halogens (e.g., iodophors), chlorine, quaternary ammonium compounds, phenolics (e.g., chlorhexidine gluconate, chloroxylenol), heavy metals, and gases.
4. High-level disinfectants (e.g., aldehydes) and autoclaving kill bacterial endospores and fungal spores.
5.
 - a. Type of organisms: Organisms vary greatly in their ability to withstand chemical and physical treatments because of their biochemical composition and various mechanisms that they can use to protect themselves.
 - b. Number of organisms: The microbial load determines the exposure time necessary for elimination of the microorganisms.
 - c. Concentration of the disinfecting agent: The amount of disinfectant needed to destroy microorganisms varies with the different agents.
 - d. Presence of organic material: Organic material such as blood, mucus, and pus affect killing activity by inactivating the disinfecting agent.
 - e. Contact time: It is critical to know what organisms may be present and the contact time to use based on the microorganism that is most resistant.
 - f. Temperature: Disinfectants as well as sterilants can be rendered inactive by too high or too low a temperature.
 - g. pH: pH can influence the activity of the disinfecting or sterilizing agent.
 - h. Biofilms: The concentration of the disinfectant may need to be increased, the contact time may need to be increased, or both.
6. The Antimicrobial Division of the EPA regulates the registration on the use, sale, and distribution of antimicrobial pesticide products for certain inanimate, hard, nonporous surfaces, or pesticide products incorporated into substances under the pesticide law, the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). An EPA registration number is granted only when the requirement of laboratory test data, toxicity data, product formula, and label copy are approved. The disinfectant label should indicate several highlighted points important in selecting the appropriate agents for the designated use. The U.S. FDA approves antiseptics through two processes: the new drug application (NDA) process or the over-the-counter (OTC) drug review known as the *monograph system*. NDAs are defined by law as being recognized as safe and effective (RASE). The approved NDA is manufacturer-specific and allows only that particular manufacturer to market the product.
7. c
8. d
9. Alcohols inactivate microorganisms by denaturing proteins. Aldehydes denature proteins and inactive nucleic acids. Iodine and chloride compounds are active based on oxidative effects. Heavy metals (e.g., silver, mercury, zinc, copper) are less commonly used today because of their toxicity; they work by combining with proteins, thereby inactivating them. The antimicrobial action of cationic detergents (e.g., benzalkonium chloride, cetylpyridinium chloride) is mediated through disruption of the cellular membrane, resulting in leakage of cell contents. Phenolics, molecules derived from phenol, work by denaturing proteins and disrupting plasma membranes. The killing mechanism of ethylene oxide is the alkylation and subsequent inactivation of nucleic acids.
10. The main goal of handwashing is to eliminate transient microbiota. Health care workers can acquire microbes, including methicillin-resistant *Staphylococcus aureus* and SARS-CoV-2 virus, during direct contact with patients or contaminated surfaces. The purpose of the surgical hand scrub and waterless surgical hand rubs is to eliminate the transient biota and most of the resident biota. Resident biota can be persistently isolated from the hands of most people. These organisms include coagulase-negative staphylococci, *Corynebacterium* (diphtheroids or coryneforms), *Propionibacterium*, and *Cutibacterium* spp. The goal of preoperative skin preparation formulations is to disinfect an intended surgical site rapidly as well as provide a high level of bacterial inactivation and persistent antimicrobial activity, up to 6 hours after skin preparation. Preoperative skin preparation products are defined as fast-acting, broad-spectrum, and persistent antiseptic-containing preparations that significantly reduce the number of microorganisms on intact skin.

13. The following questions are asked as each specimen culture is examined:
 - What is the specimen source?
 - Does this source have normal biota, or is it a sterile source?
 - If normal biota is present, what bacteria are found, and what do these colonies look like?
 - What are the most likely pathogens in this specimen?
 - What is the colony morphology of these pathogens?
 - Which medium is demonstrating growth, and what is the purpose of the medium?
14. Many laboratories use the Maki roll technique to culture a vascular catheter tip. A segment of the catheter tip is rolled across the surface of a blood agar plate. The plate is incubated, and testing is performed on each organism that produces 15 or more colonies.
15. The role of the microbiology laboratory in the postanalytic process is to communicate accurate and timely information. Preliminary results are often reported as the information becomes available. The laboratory report must be clear and understandable; interpretive statements may be necessary. Critical values must be reported to the health care provider immediately.

2. SBA is a nonselective medium that supports the growth of gram-positive and gram-negative bacteria. MAC is a selective medium that inhibits the growth of gram-positive bacteria and allows gram-negative bacilli to grow. One of the three isolates on the SBA plate is gram-positive and cannot grow on MAC agar.
3. a
4. They generally produce clear, colorless colonies on MAC agar.
5. β -Hemolysis is complete hemolysis of the red blood cells in the agar, showing a clear zone around the colony. α -Hemolysis is incomplete hemolysis of the red blood cells, showing a green discoloration around the colony.
6. "Puffballs" in broth media usually suggest the presence of certain streptococcal species.

11. Two important enzymes necessary for the rapid metabolism of lactose are lactose (β -galactoside) permease and β -galactosidase. The permease enzyme facilitates the uptake of lactose. Delayed lactose fermenters lack permease but contain β -galactosidase. It takes delayed lactose fermenters longer to transport lactose across the cell wall and plasma membrane. Acid formation can be delayed until 48 to 72 hours.
12. No color change after the addition of the reagents indicates that nitrite (NO_2) is not present. Two explanations are that the bacterium was unable to reduce nitrate (NO_3) or the bacterium reduced nitrate to nitrite and then to nitrogen gas (N_2). Zinc dust reduces nitrate to nitrite. If, after the addition of zinc dust, the broth still does not change color, then the nitrate had been totally reduced by the bacterium to nitrogen gas. If color forms after the addition of zinc dust, then the nitrate had not been reduced by the bacterium, and this is a true-negative result.

11. Double immunodiffusion is a precipitation reaction performed in an agarose matrix. The antigen and specific antibody are placed in separate nearby wells, and both diffuse through the agarose. At the zone of equivalence, a visible precipitate is formed. With single radial immunodiffusion, antibody is evenly distributed in an agarose matrix. Corresponding antigen is added to wells in the agar. The antigen diffuses through the agar, and a concentration gradient is produced. At the zone of equivalence, a visible precipitate is formed. The diameter of the precipitation ring is proportional to the concentration of the antigen.
12. False-negative test results can be the result of: (1) immunocompromised patients not being able to produce detectable antibody levels; (2) the sample being collected too early in the course of the infection (in some diseases, it may take a long time to form antibodies); (3) the diagnostic kit having too high a concentration of antigen (postzone phenomenon); or (4) the presence of a heterophile antibody in the patient sample binding to the antigen in the test kit blocking specific antibody from binding.
13. During passive agglutination, an antigen is bound to a carrier particle, such as latex beads. When the carrier particles are mixed with a clinical sample, agglutination will occur if the corresponding antibody is present. With reverse passive agglutination, antibody is fixed to the surface of a carrier particle. When the carrier particles are mixed with a clinical sample containing the corresponding antigen, agglutination occurs.
14. There are two major serotypes of HIV: 1 and 2. The vast majority of cases in the United States are caused by HIV-1, while HIV-2 is found predominantly in Africa. However, because of international travel, clinical laboratories must screen for both serotypes. Because it takes most patients several weeks to produce detectable antibodies to HIV, it is also important to test for the antigen p24. This is often the first positive marker in patients with HIV infection.

1. Viridans streptococci are normal microbiota in the throat. Reporting antimicrobial susceptibility test results often suggests to the health care provider that the isolated organism is clinically significant, and antimicrobial therapy should be considered. Reporting antimicrobial susceptibility results on viridans streptococci from the throat may lead to inappropriate use of antimicrobial agents and may also prevent the health care provider from finding the correct cause of the patient's problem.

1. *Staphylococcus aureus* is noted for causing suppurative skin infections such as bullous impetigo; furuncles (boils); carbuncles; cellulitis; wound infections associated with trauma, surgery, and burns; pneumonia; organ abscesses; bacteremia; endocarditis; osteomyelitis; and septic arthritis.
2. Although *S. aureus* has had a lengthy association with hospitalized and nursing home patients, recovery in community populations, including pediatric populations and student athletes, has increased.
3. Protein A binds the Fc portion of immunoglobulin G (IgG), thereby interfering with phagocytosis and blocking the protective action of IgG.
4. Toxic shock syndrome (TSS) is associated mainly with TSST-1. However, some cases of TSS have been linked to enterotoxin B or C.
5. Exfoliative toxin or epidermolytic toxin causes staphylococcal scalded skin syndrome.
6. Enterotoxins A to E and G to J, most commonly A and D, are associated with staphylococcal food poisonings.
7. Although not all coagulase-negative staphylococci (CoNS) are considered clinically significant, those CoNS associated with indwelling devices and immunocompromised patients are considered potential pathogens. *S. lugdunensis* infections are usually more invasive. Also, because they have a distinct susceptibility category separate from the other CoNS, it is important to identify suspected *S. lugdunensis* to the species level, as in the case of blood isolates. Urinary tract infections caused by *S. saprophyticus* are also clinically significant.
8. The clinically significant CoNS include *S. epidermidis* and *S. saprophyticus*. In addition, infections (e.g., endocarditis, septicemia, peritonitis) caused by *S. haemolyticus* and *S. lugdunensis* have become more common. *S. saprophyticus* is clinically significant when isolated from urine. Other CoNS, such as *S. pseudintermedius*, will gain importance as they become more frequently recovered and identified using the latest techniques.
9. Tube-coagulase and clumping factor (slide) coagulase are two tests used to detect coagulase activity of *S. aureus*. The tube-coagulase can be used as a confirmatory test for coagulase, whereas the traditional slide coagulase using plasma is considered obsolete.
10. A positive coagulase test would differentiate *S. aureus* from most other staphylococci. Numerous commercial kits contain plasma-coated latex particles or antibodies directed against *S. aureus* molecules that also accurately identify the organism.
11. A disk diffusion test using a 5- μ g novobiocin disk can be used. *S. saprophyticus* will be resistant, whereas most other CoNS will be susceptible.
12. An oxacillin-resistant *S. aureus* isolate is considered resistant to all penicillinase-stable penicillins and most β -lactam antibiotics. Such an isolate is referred to commonly as methicillin-resistant *S. aureus* (MRSA).
13. Those who are at high risk for healthcare-associated MRSA include recently hospitalized patients, especially older adults; people with weakened immune systems; individuals who reside in nursing homes; and patients who have an invasive medical device such as an intravenous line or urinary catheter that can provide a pathway for MRSA to travel into the body. Those who participate in sports or live in crowded or unsanitary conditions are at risk for community-associated MRSA infections. Outbreaks of MRSA have occurred in military training camps, childcare centers, and jails. Carriers of MRSA can spread the bacteria, even if they are not ill themselves.
14. Oxacillin has been used to predict methicillin resistance. However, ceftiofur is now recommended for determining oxacillin resistance in staphylococcal species. For the most accurate detection of methicillin resistance, molecular tests for *mecA* or tests that detect the *mecA* product, PBP2, may be used. For detection of clindamycin resistance, a disk diffusion induction test (D-zone test) of clindamycin and erythromycin should be used. Not all susceptibility methods are able to detect vancomycin-intermediate *S. aureus* (VISA) or vancomycin-resistant *S. aureus* (VRSA). The Clinical and Laboratory Standard Institute and Centers for Disease Control and Prevention have recommended the addition of a vancomycin agar plate, which can be used as a supplemental plate when testing MRSA isolates. Most VISA and VRSA have thus far been detected in these more resistant *S. aureus* strains.
15. Clinical isolates that have been grown on traditional media can be rapidly identified by simple catalase and latex agglutination tests, as described in this chapter. For many laboratories, this will continue to be a cost-effective and efficient way to identify *S. aureus* and CoNS.
16. A Gram stain and catalase test are two initial rapid tests important in determining the presence of staphylococci. Next, a slide latex or hemagglutination assay should be performed. The third-generation tests detect protein A, clumping factor, and capsular polysaccharide serotypes 5 and 8. A positive result indicates *S. aureus*. A negative result suggests a coagulase-negative staphylococci. Laboratories are incorporating molecular tests to identify staphylococci. These methods will provide rapid methods of identification within hours, and they can identify markers of antimicrobial resistance. Matrix-assisted laser desorption/ionization-time-of-flight mass spectrometry with databases incorporating commonly recovered species of staphylococci will also become an asset, especially in larger institutions.

5. a
6. Penicillin is the drug of choice for the treatment of *S. pyogenes* pharyngitis. Patients who are allergic to penicillin are often treated with erythromycin.
7. *S. pyogenes* has been linked to necrotizing fasciitis. Streptococcal toxic shock syndrome is a systemic disease mediated by a soluble toxin. The infective agent in this case is not necessarily invasive. Rheumatic fever and acute glomerulonephritis are immunologic sequelae and not invasive infections.
8. *S. pneumoniae* is the most common cause of community-acquired pneumonia and of bacterial pneumonia.
9. Group B streptococci (*S. agalactiae*) are rarely associated with disease in healthy adults; however, they are a significant cause of morbidity and mortality in neonates. Neonates can acquire infection in utero following premature rupture of the membrane or during delivery. Pregnant women are often screened for group B streptococci as part of the prenatal workup.
10. Members of the genera *Granulicatella* and *Abiotrophia*, formerly referred to as *nutritionally variant streptococci*, have a requirement for pyridoxal. Isolates are generally able to grow in blood cultures, but agar must be supplemented with pyridoxal to sustain growth on solid media. Alternatively, the bacteria can grow as small pinpoint colonies around colonies of *Staphylococcus aureus*, which secretes small amounts of pyridoxal during growth.

13. a
14. *Moraxella catarrhalis* will grow on SBA and CHOC agar, producing smooth, opaque, gray to white colonies. Identification tests will show that *M. catarrhalis* is oxidase- and catalase-positive. The organism is asaccharolytic, and it may be differentiated from *Neisseria* spp. by positive DNase or butyrate esterase reactions. Several of the commercial multitest systems for the identification of *Neisseria* species also identify *M. catarrhalis* (see Table 17.3).
15. b

Chapter 18

1. *Haemophilus influenzae* will grow only where both X and V factors are present; therefore the bacteria will grow between the two strips where the two factors have diffused and around the XV strip.
2. b
3. a
4. *H. ducreyi* is fastidious and requires enriched media for growth. GC agar supplemented with 1% hemoglobin, 5% fetal calf serum, 1% IsoVitaleX, and 3 mg/L of vancomycin is recommended. The plates must be incubated in an atmosphere of increased humidity and CO₂ (5% to 10%) and at a temperature of about 32° C.
5. Both *H. aegyptius* and *H. influenzae* biogroup aegyptius are noted for causing conjunctivitis. *H. influenzae* biogroup aegyptius, however, is associated with a more invasive disease known as *Brazilian purpuric fever* characterized by conjunctivitis, high fever, vomiting, petechiae, purpura, septicemia, and shock.
6. b
7. d
8. a
9. *Brucella melitensis* will grow on SBA and does not require X or V factor, whereas *H. influenzae* will not grow on SBA and does require X and V factors.
10. *Francisella tularensis* is the most likely causative agent. The primary reservoirs for *F. tularensis* are rabbits. Although some infections are acquired by ingestion,

it is more common to find ulceroglandular infections following direct contact with rabbits.

11. Travel, age (older adults), smoking, alcohol consumption, and an immunocompromised state are risk factors that contribute to severe infections caused by *Legionella* spp.
12. Crowded conditions and warm, humid, environmental sources contribute to infections by *Legionella*. Infections are often linked to contaminated water supplies.
13. Buffered charcoal yeast extract with 0.1% α -ketoglutaric acid (BCYE α) agar is the preferred medium for the recovery of *Legionella* spp.
14. Chlorine tolerance below 2 to 3 mg/L, ability to grow at 20° to 43° C and survive for varying periods at 40° to 60° C, capability to adhere to components of piped water systems, ability to survive in the presence of environmental bacteria and algae, and ability to multiply within free-living protozoa are factors contributing to human infections caused by *Legionella* spp.
15. Urine for the urine antigen test is the best nonrespiratory specimen for the detection of *Legionella* spp.
16. Presumptive identification methods include Gram staining a suspicious colony growing only on BCYE α medium and finding thin, faintly-staining gram-negative rods that may show size variation, from 2 to 20 μ m in length. Also, a test for L-cysteine requirement by subculturing to BCYE α and SBA should be performed. Bacteria demonstrating a requirement for L-cysteine should be typed using anti-*Legionella* antisera.
17. c
18. No, despite vaccination as children, adults are not immune; however, infections in adults are normally mild or asymptomatic. Adults serve as reservoirs for disease in children and adolescents.
19. Nasopharyngeal aspirates and Dacron swabs are the clinical samples of choice for the diagnosis of *B. pertussis* infection.
20. Amies, casamino acid, and Regan-Lowe with charcoal and cephalixin transport media are the most appropriate for the maximum recovery of *B. pertussis*. Direct inoculation of plated media at bedside is preferred over transport media.
21. PCR testing is the most widely accepted method for rapid detection of *B. pertussis*.
22. Both species cause pertussis in children; however, pertussis caused by *B. parapertussis* tends to be milder.
23. No, serologic testing is not widely available, but it can be used as a retrospective epidemiologic tool.
24. c
25. b

Chapter 19

1. Most members of the order Enterobacterales can ferment glucose, are oxidase-negative (except for *Plesiomonas shigelloides*), and are able to reduce nitrate to nitrite (except for *Photobacterium* spp. and *Xenorhabdus* spp.).

9. Appropriate specimens for the isolation of enteric campylobacters are stool samples and rectal swabs; stool samples are preferred. Two categories of media are available for isolation: blood-based and charcoal-based media. A commonly used blood-based medium is CAMPY-BAP. This is a *Brucella* agar-based medium, with 10% sheep red blood cells and a combination of antimicrobials. Charcoal cefoperazone desoxycholate agar is an alternative. The addition of antimicrobial agents and incubation of the plates at 42° C inhibits normal fecal biota. Because the campylobacters require oxygen at a concentration less than room air, they must be incubated in a microaerophilic atmosphere.
10. The most commonly used nonculture method for the diagnosis of *Helicobacter pylori* is the noninvasive ¹³C-labeled urea breath test. The patient receives an oral dose of labeled urea. Urease activity by *H. pylori* results in the formation of radioactive-labeled CO₂, which is absorbed into the bloodstream and then exhaled. Other nonculture methods include microscopic examination of stained gastric tissue, direct fecal antigen detection, polymerase chain reaction assay, and determining urease activity of gastric biopsy material.

6. c
7. *Pseudomonas aeruginosa*, *Acinetobacter baumannii* complex, *Burkholderia* spp., and *Stenotrophomonas maltophilia* are the four most common nonfermentative, gram-negative bacilli isolated in the clinical laboratory. *P. aeruginosa* is the most common nonfermenter associated with clinical infections, especially healthcare-associated infections. *A. baumannii* complex, *Burkholderia* spp., and *S. maltophilia*

are often isolated from hospitalized patients, especially from respiratory specimens, but they are more often colonizers and are not always clinically significant. The isolation of a nonfermenter from a single blood culture or as part of a polymicrobial infection often indicates that the organism is acting as a colonizer or a laboratory contaminant rather than a relevant pathogen. However, if one of the nonfermenters is seen on a Gram-stained smear from a sterile site, is the only organism isolated, and is present in high numbers, its clinical significance must be considered.

8. Many of the nonfermenters, especially *P. aeruginosa*, *A. baumannii* complex, and *S. maltophilia*, can be resistant to agents used to treat infections caused by fermentative gram-negative bacilli. They are resistant to penicillin, ampicillin, most third-generation cephalosporins (except ceftazidime), macrolides, lincosamides, and agents active against gram-positive bacteria. There is variability of their in vitro and in vivo responses to aminoglycosides; quinolones; aminopenicillins, such as piperacillin and ticarcillin; and sulfamethoxazole. Specific susceptibility tests must be performed if the nonfermenter is considered clinically relevant.

11. The infant in the Case in Point was infected with *Chlamydia trachomatis*. This organism can cause a variety of infections in neonates, including pneumonia and pharyngeal and enteric infections.
12. Lymphogranuloma venereum differs from other diseases caused by *C. trachomatis* because the serovars causing this disease are more invasive. These serovars can survive inside mononuclear cells and are carried into the lymphoid tissue, where they produce a strong inflammatory response.
13. *Chlamydia pneumoniae* is thought to be a common cause of pharyngitis and pneumonia. This organism might be associated with atherosclerosis and coronary heart disease.
14. *Coxiella burnetii* is a facultative intracellular parasite that develops within the phagolysosome of infected cells. *Rickettsia* spp. prevent phagolysosome formation and escape the phagosome and replicate free in the cytoplasm. In addition, although *C. burnetii* is known to infect more than 12 genera of ticks and other arthropods, it is generally not transmitted by arthropods. *C. burnetii*, unlike the *Rickettsia* spp., has been grown in cell-free media.

6. Because of their fastidious nature, routine prenatal cultures would not have detected most mycoplasma. *Mycoplasma hominis* will grow on routine media, but it forms pinpoint colonies after 48 hours of incubation that could be easily missed unless efforts were made to specifically detect this agent.
7. The four species of mollicutes associated with the urogenital tract of humans are *M. hominis*, *M. genitalium*, *Ureaplasma urealyticum*, and *U. parvum*.
8. A7 and A8 are selective and differential media for the isolation of *M. hominis* and *U. urealyticum*. In addition,

Shepard's 10B arginine broth can also be used. *M. hominis* and *M. pneumoniae* can be grown on SP4 broth if arginine is added for the latter. *M. hominis* is the least fastidious of the mollicutes and will grow on sheep blood and chocolate agars.

9. The mollicutes do not cause vaginitis. However, there is evidence that *M. hominis* can contribute to bacterial vaginosis. *M. hominis* has also been isolated from the endometrium and fallopian tubes of women with salpingitis. Meningitis in neonates caused by *M. hominis* and *U. urealyticum* has been reported. Infection could have originated during delivery.
10. Complement fixation assays had been the primary serologic method to detect anti-*M. pneumoniae* antibodies. However, because of technical problems, enzyme immunoassays and immunofluorescent antibody methods are now more commonly used.
11. The mollicutes lack a cell wall and are therefore inherently resistant to the β -lactams: penicillins and cephalosporins.

9. d
10. Many mycobacterial species, saprophytes, and potential pathogens may be isolated from humans. Historically, mycobacteria have been identified by growth characteristics and biochemical testing. More recently, molecular biology assays have been developed. These assays include mycolic acid analysis of bacterial cell walls by high-pressure liquid chromatography, DNA probe technology, DNA sequencing, and MALDI-TOF MS. Genetic probe technology offers tremendous promise in microbial identification at a variety of levels—family, genus, species, and subspecies. The most common probe technology is the commercially available, single-stranded, acridinium ester–labeled DNA probe for the detection of rRNA (Gen-Probe, San Diego, CA). Probes specific for the *M. tuberculosis* complex, *M. kansasii*, and *M. gordonae* and separate probes for *M. avium* and *M. intracellulare* are available. Laboratories should perform identification according to the level of service for which they are qualified. All isolates should be identified to the species level.
11. Slowly growing *M. tuberculosis* has the extraordinary ability to persist and replicate in the harsh environment of the alveolar macrophage. The pathogenic mycobacteria are slow growers, which also lends to drug resistance. Antimicrobial agents are more active against rapidly growing bacteria. The American Thoracic Society, Centers for Disease Control and Prevention, and the International Union Against Tuberculosis and Lung Disease recommend a regimen of rifampin, isoniazid, pyrazinamide, and ethambutol (RIPE treatment) for the first 8 weeks for treatment of tuberculosis. This is followed by isoniazid and rifampin for 18 weeks. Multidrug-resistant tuberculosis, defined as an isolate resistant to at least isoniazid and rifampin, is more complicated to treat.
12. Mycobacteriologic services are available in many laboratories. Clinical laboratory functions that contribute to the diagnosis and management of tuberculosis have been divided into the following three major categories of service offered.
 - Level 1: Collection and transport of specimens and preparation and examination of smears for acid-fast bacilli.
 - Level 2: Procedures of level 1, plus isolation and identification of *M. tuberculosis*.
 - Level 3: All procedures of level 2, plus identification of mycobacteria other than *M. tuberculosis*.
 The determination of drug susceptibility may be performed at level 2 and should be performed at level 3. However, antimicrobial susceptibility testing of the mycobacteria is difficult and should be attempted only by laboratories with experience in this assay. A laboratory may choose to develop or maintain the skills defined under one of the aforementioned levels, depending on the frequency with which specimens are received for isolation of mycobacteria, the nature of the clinical community being served, and the availability of a specialized referral service. All laboratories that perform clinical mycobacteriology should participate in recognized proficiency testing programs, and levels of service should be established and limited by the quality of performance demonstrated in these examinations.
13. Many clinical specimens contain an abundance of nonmycobacterial microorganisms. Unless an attempt is made to inhibit these usually fast-growing contaminants, they can quickly overgrow the more slowly growing mycobacteria. Organic debris (e.g., tissue, serum, other proteinaceous material) surrounding the organism in the specimen must also be liquefied so decontaminating agents will kill undesirable microbes, allowing surviving mycobacteria to gain access to the nutrients in the media. Mycobacteria are slightly more refractory to harsh chemicals; therefore chemical digestion and decontamination procedures have been used with success to enhance the recovery of acid-fast bacteria from clinical specimens. NaOH digests and decontaminates specimens, whereas *N*-acetyl-L-cysteine effectively digests the specimen but does not decontaminate.
14. Because low levels of mycobacteria organism may be present in clinical samples, meticulous care must be practiced during the processing of specimens for the detection and isolation of mycobacterial organisms. False-negative results may occur if processing protocols are not followed appropriately. Prolonged decontamination can have a negative effect by killing the mycobacteria. Improper centrifugation force may also lead to false-negative results. If insufficient force is applied, the mycobacteria may remain in the interface of the processed specimen and can be inadvertently discarded during processing. Care must be applied during culturing of the specimen. False-positive results may occur through carryover from the mouths

of containers used to transfer processing agents, introduction of the organism from environmental sources, such as water, or introduction of organisms from aerosols produced when specimen containers are opened. When making slides, care must be taken to prevent carryover from one slide to another. Slides should never come into contact with one another.

Cross-contamination between specimens may occur if instruments are not properly maintained.

15. The mycobacteria are easily spread by the airborne route; therefore it is important to avoid aerosol-generating procedures. In addition, mycobacterial laboratories should be under negative air pressure so air flows inward when the doors to the laboratory are opened. Specimen processing should be conducted in a biological safety cabinet; laboratory scientists must wear laboratory coats, eye protection, and a respirator (not a surgical mask). When disposable inoculating loops and needles are not used, electric incinerators should be used instead of open flames for sterilizing metal loops and needles. When specimens are centrifuged, they must be in a screw-capped tube in a secondary screw-capped container.

Chapter 27

1. d
2. b
3. b

4. a. *Blastomyces dermatitidis*: Microscopic examination of cultures grown at 35° C reveals large, broad-based budding yeast. At 22° C, the microscopic examination of the mold reveals conidia borne on short lateral branches that are ovoid to dumbbell-shaped and varying in diameter from 2 to 10 µm.
b. *Coccidioides immitis* and *C. posadasii*: Microscopic examination of secretions may reveal spherules containing endospores. At 22° C, microscopic examination of the mold reveals alternating (separated by a disjunct cell) hyaline arthroconidia.
c. *Histoplasma capsulatum*: Microscopic examination of cultures grown at 35° C reveals small yeast cells. The yeast cells measure 2 to 3 µm by 4 to 5 µm. At 22° C, microscopic examination of the mold reveals nondescript spherical microconidia and characteristic tuberculate macroconidia.
d. *Sporothrix schenckii*: Microscopic examination of cultures grown at 35° C reveals small, cigar-shaped yeast cells. Microscopic examination of the mold phase reveals conidia developing in a rosette pattern at the ends of delicate conidiophores in addition to dark-walled conidia being produced along the sides of the hyphae.
5. a. *Nannizzia gypsea*: Microscopic examination reveals fusiform, moderately thick-walled conidia measuring 8 to 15 µm by 25 to 60 µm, with as many as six cells. In some isolates, the distal end of the macroconidium may bear a thin, filamentous tail.
b. *Microsporium canis*: Microscopic examination reveals spindle-shaped macroconidia with echinulate, thick walls measuring 12 to 25 µm by 35 to 110 µm with 3 to 15 cells. The tapering, sometimes elongated, spiny distal ends of macroconidia are key features that distinguish this species.
c. *Trichophyton rubrum*: Microscopic examination reveals clavate or peg-shaped microconidia formed along undifferentiated hyphae. Rare macroconidia may be formed.
d. *Trichophyton mentagrophytes*: Globose microconidia are found primarily in clusters described as grapelike or engrape. Macroconidia are thin-walled, smooth, and cigar-shaped, with four to five cells separated by parallel cross walls.
6. *Trichophyton rubrum* is urease-positive, whereas *T. mentagrophytes* is typically urease-negative. Wedge-shaped perforations in the hair shaft (positive) are characteristic of *T. mentagrophytes* as well as *M. canis* and *M. gypseum*. Species negative for hair perforation include *T. rubrum*, *M. audouinii*, and *M. praecox*.
7. a
8. Saprobies are usually environmental contaminants and are not considered human pathogens. However, saprobies may cause disease in individuals with impaired immune systems. When a saprobe is recovered from an immunocompromised patient, the laboratory should work closely with the physician to help determine if the isolate is an environmental contaminant, or if it is possibly causing disease.
9. *Penicillium* spp. and *Aspergillus fumigatus* can form blue-green colonies, but they may be differentiated microscopically in that conidia in the aspergilli are formed from phialides attached to a vesicle or metula, whereas conidia in the genus *Penicillium* are formed from branched conidiophores bearing phialides at their tips. *Fusarium* spp. are typically white to pink to purple colonies that produce large, hyaline, thin canoe- to green bean-shaped macroconidia. *Curvularia* spp. have black colonies that produce wide, phaeoid (dematiaceous), crescent to half circle-shaped conidia.
10. Lesions of chromoblastomycosis most often appear as verrucous nodules that may become ulcerated and crusted. Long-standing lesions have a cauliflower-like surface. Brown, round, sclerotic bodies, which are nonbudding structures occurring singly or in clusters, are seen in tissues. These sclerotic bodies reproduce by dividing in various planes, resulting in multicellular forms. Lesions of mycetoma are characterized by tumefaction, draining sinuses, and granules. Mycetomas are localized infections that involve the cutaneous and subcutaneous tissue, and possibly bone. Granules are released through the draining sinus tracts.
11. Fungi are eukaryotic and possess a true nucleus, with a nuclear membrane and organelles like mitochondria. Bacteria are prokaryotic and lack these structures. Unlike plants, fungi lack chlorophyll and do not undergo photosynthesis and must absorb nutrients from the environment. In addition, fungal cell walls are made of chitin, whereas those of plants contain cellulose. Bacteria lack chitin and cellulose.
12. Fungal colonies, although occurring in many colors, may be generally divided as hyaline or phaeoid. Hyaline molds are light-colored, whereas phaeoid fungi are darkly pigmented. This pigmentation is a result of

melanin in the cell wall of the organism. The Fontana-Masson stain will detect phaeoid hyphae in the tissues because it stains melanin.

13. Teleomorph is the sexual stage of a fungus, whereas the anamorph is the stage that reproduces asexually. In certain species, more than one asexual stage is associated with the same teleomorph. When more than one anamorph exists, they are termed *synanamorphs*.
14. The germ tube test would be positive within 2.5 to 3 hours, and the cornmeal agar would result in true hyphae and pseudohyphae, with rare chlamydoconidia.

Chapter 28

1. The most likely identification is *Giardia duodenalis*; these parasites are pathogenic for humans.
2. Both thick and thin smears are routinely performed on blood specimens to detect parasites. Because the thick smear is made with a larger volume of blood, it is more sensitive than a thin smear. However, species identification is made from the thin smear because the red blood cells are intact and parasites have a more characteristic morphology.
3. The eggs of *Taenia* spp. are round, are approximately 35 μm in diameter, have a striated border, and contain a hexacanth oncosphere. The eggs of *T. solium* and *T. saginata* cannot be differentiated. *A. lumbricoides* eggs are fertilized or unfertilized. The fertilized eggs are slightly oval, with a thick mammillated coat, and they measure about 75 μm $\times$ 50 μm . The unfertilized eggs are more oval and are as long as 90 μm , with a thick mammillated coat or an extremely minimal mammillated layer. Eggs of *T. trichiura* are oval with plugs on both poles; they are about 52 μm $\times$ 22 μm . Hookworm eggs are oval with broad ends, have a clear space between the thin shell and embryo, and measure 55 to 75 μm $\times$ 35 to 40 μm . The eggs of the three human hookworm species, *Ancylostoma duodenale*, *Necator americanus*, and *Ancylostoma ceyanicum* cannot be differentiated.
4. The gravid females of *E. vermicularis* (pinworm) migrate out of the anus to deposit eggs; therefore stool samples are not the specimen of choice. The best method for detection of pinworm eggs is to use the scotch tape or sticky paddle technique.
5. *C. cayetanensis* oocysts are round and average 8 to 10 μm in diameter. On a wet mount, they appear nonrefractile, with a cluster of granules. The organisms are not readily distinguishable on trichrome-stained smears and may appear as round, wrinkled, clear objects. With modified acid-fast stain, the organisms stain variably from dark pink to almost colorless and may have a wrinkled or distorted shape. Oocysts of *Cyclospora* autofluoresce blue under ultraviolet light, at a wavelength of 365 nm, and green at 450 nm. *C. parvum* oocysts are round and approximately 4 to 6 μm in diameter. Because of their small size, they are not distinguishable on wet mounts or in most permanent-stained smears. With a modified acid-fast stain, they are dark pink and round. Direct fluorescent antibody techniques that detect the oocyst in the feces are available.
6. The most likely identification is *Entamoeba histolytica* trophozoite. If no ingested erythrocytes had been seen, the organism would have been reported as *E. histolytica*-*E. dispar* because the organisms are morphologically identical. The nonpathogenic *Entamoeba moshkovskii* and *Entamoeba bangladeshi* are also morphologically indistinguishable from *E. histolytica*. The presence of ingested erythrocytes indicates that it is *E. histolytica*. This parasite is considered pathogenic for humans. Patients with *E. histolytica* infection can suffer from amebic dysentery, which can manifest as fever and intense colicky abdominal pain.
7. *C. parvum* produces two types of oocysts, thin-walled and thick-walled. The thick-walled oocysts are passed in the feces and are infective. The thin-walled oocysts are involved in autoinfection. These structures rupture in the intestine and release sporozoites that reinfect intestinal cells. With *S. stercoralis* infection, the eggs rupture in the intestine and release rhabditiform larva that mature to filariform larva in the intestine. The filariform larvae burrow into the intestinal wall, gain access to the circulation, and then complete the life cycle. Autoinfections result in persistent infections with large numbers of parasites.
8. The organism belongs to the genus *Trypanosoma*. The morphologic form is the trypomastigote. Members of the genus *Trypanosoma* cause African (trypanosomiasis) sleeping sickness, transmitted by tsetse flies, and Chagas disease, transmitted by kissing or reduviid bugs.
9. Primary amebic meningoencephalitis is caused by *Naegleria fowleri*. Young, healthy individuals are usually infected and present with a history of swimming in warm, stagnant water. The trophozoite gains direct access to the brain via the nasal olfactory nerve when water is forced into the nose. The infection has a rapid onset (within 2 to 7 days) after exposure, and symptoms resemble those of bacterial meningitis—photophobia, headache, vomiting, and stiff neck. Death usually occurs within 1 week of onset of symptoms. Diagnosis can be made by observing the ameboid trophozoite in a wet mount of the CSF sediment. Trophozoites may be found in biopsy tissue of the brain. Granulomatous amebic encephalitis is a chronic infection caused by *Acanthamoeba* spp. and *Balamuthia mandrillaris* and is usually found in individuals with underlying conditions such as lymphoma or diabetes. The organism may enter through the skin or be inhaled, and it spreads hematogenously to the brain. It may take years for symptoms to develop. Symptoms include headache, dizziness, mental confusion, and seizures. Often, the infection is detected at autopsy. Trophozoite and cyst forms can be identified on biopsy specimens.
10. Toxoplasmosis in the immunocompetent host is usually asymptomatic or presents as a transient, flulike illness. The immunocompromised patient often develops encephalitis or pneumonia. *Cryptosporidium* infection in the immunocompetent host causes self-limiting diarrhea. In the immunocompromised host,

the diarrhea is prolonged and severe (partially because of the autoinfective part of the life cycle). The patient may lose as much as 10 L/day of fluid and develop electrolyte imbalance. Long-term infection may lead to malabsorption syndrome. *Strongyloides* infection in the immunocompetent host also may be asymptomatic or present with vague abdominal symptoms that can mimic those of an ulcer. In the immunocompromised host, hyperinfection (dissemination) may result, with filariform larvae migrating to multiple body organs.

11. Some opportunistic infections and conditions associated with AIDS include esophageal candidiasis, cryptococcal meningitis, cryptosporidiosis, histoplasmosis, persistent HSV infections, mycobacterial infections, *Pneumocystis* pneumonia, and Kaposi sarcoma.
12. Testing for HIV-specific antigens and antibodies is important in the diagnosis of HIV infection, including antibodies to viral antigens p24, p31, gp41, and gp120/160 and HIV p24 antigen.
13. EBV causes infectious mononucleosis. EBV has been associated with Burkitt lymphoma, nasopharyngeal carcinoma, and the development of B-cell lymphoproliferative disorder or lymphoma. Other EBV complications include splenic hemorrhage, hepatitis, thrombocytopenia purpura with hemolytic anemia, Reye syndrome, and encephalitis.
14. Signs and symptoms of acute HBV infection include fever, anorexia, and hepatic tenderness, with jaundice occurring in 30% to 50% of infected older children and adults. The immune response slowly clears HBV from the body, and most patients become noninfectious. Some patients become HBV carriers for longer than 6 months, and these patients are very likely to carry the virus for much longer. Chronic hepatitis patients have a higher risk of cirrhosis or hepatic carcinoma. Acute hepatitis resolves as HBsAg clears, and anti-HBs can be detected. As infection resolves, HBeAg fades, and anti-HBe appears. In chronic hepatitis patients, HBsAg persists,

and the corresponding antibody cannot be detected. Similarly, HBeAg can persist.

15. Dengue fever (DF) is a fairly mild, self-limiting disease, with patients experiencing fever, headache, myalgia, and bone pain. Dengue hemorrhagic fever is a serious infection, and these patients develop the symptoms of classic DF along with thrombocytopenia, hemorrhage, and shock. Death can result from the infection.
16. Fluorescent antibody and ELISA methods are available for the rapid detection of rabies antigen in brain tissue and are the preferred methods. A classic method for the diagnosis of rabies was to detect Negri bodies, eosinophilic cytoplasmic inclusions, in neurons. This test is insensitive and no longer recommended.
17. Many human papillomaviruses (HPVs) cause plantar, common, and genital warts. Some strains are associated with a rare autosomal disease called *epidermodysplasia verruciformis*, and some are associated with cervical cancer. A vaccine (Gardasil-9) is available for some of the strains associated with cervical cancer.
18. The viruses most noted for latency are the herpesviruses.
19. Influenza viruses mutate often because of replication errors. These mutations cause antigenic drift, ensuring antigenic variability of strains each year. Recombination events of the influenza A genome result in a major antigenic change called *antigenic shift*. Health care agencies predict the most likely strains that will predominate in the next season. Quadrivalent influenza vaccines are available before the start of the influenza season. Although this process is successful, occasionally an unexpected strain will predominate, and the vaccine may not provide total coverage for that strain. Even with this known possibility, it is still advised that all persons be vaccinated because some protection is better than no protection.
20. Messenger RNA (mRNA) vaccines have provided the best immunity against coronavirus 2, the cause of coronavirus disease 2019. The vaccine contains mRNA that directs the production of a viral spike protein. Antibody to the spike protein is protective.

13. Advances in scientific technology and greater understanding of the virulence mechanisms of *Bacillus anthracis* have led to the ability to weaponize this organism, making it much easier to disseminate throughout the population as opposed to natural means of infection. Smallpox was declared eradicated in 1979,

so very few individuals since then have been vaccinated. The known threat of existing smallpox strains that could be released into such a naive population could affect millions of people and devastate national health care infrastructures.

14. LRN reference laboratories use standardized reagents and controls and agent-specific protocols for the confirmatory identification of several biothreat agents. They are the laboratories that respond to a sentinel laboratory request for identification.
15. Tier 1 agents are considered to be the highest risk to the public and national security because of their ease in dissemination and transmission and known high morbidity and mortality rates, aimed to cause public panic and social disruption. Agents in the non-Tier 1 group have lower mortality rates and are moderately easy to produce and disseminate.
16. a. *Bacillus anthracis* grown on sheep blood agar plates are characterized as large (2 to 5 mm), flat, irregularly round colonies with a wavy border (Medusa head) and a ground-glass appearance. Colonies are nonhemolytic and are tenacious (stiff egg whites). Gram-stained smear shows large, gram-positive rods. The organism is nonmotile and catalase-positive.
- b. *Yersinia pestis* is a slow-growing organism and will appear pinpoint in size on sheep blood agar or MacConkey agar plates. Usually, 48 hours of incubation is required to identify the organism. It is a nonlactose fermenter. Gram-stained smear may show small, bipolar, gram-negative rods (safety pin appearance). Essential biochemical reactions are oxidase negative, catalase positive, indole negative, and urease negative.
- c. *Francisella tularensis* is a slow-growing organism that must be incubated up to 48 hours on primary plates to produce visible growth. This organism has a requirement for cysteine and thus will not grow very well on sheep blood agar. Chocolate agar or a similar medium will allow growth. Colonies appear pinpoint grayish white after 48 hours. It is a faintly staining, gram-negative coccobacillus. Essential biochemical reactions are oxidase negative, catalase weak positive, β -lactamase positive, satellite test negative, and urease negative.
- d. *Burkholderia* spp. are very slow-growing organisms, requiring up to 72 hours to form mature colonies. They are gram-negative rods. Key biochemical reactions include oxidase variable, catalase positive, indole negative, and resistance to colistin.
17. a. For Ebola virus and Marburg virus, specimens include serum, heparinized plasma, or whole blood collected during the acute febrile stages of illness. Additionally, spleen, lymph nodes, liver, and kidney obtained at autopsy may also be submitted.
- b. To detect *Clostridium botulinum* toxin, specimens include feces, enema fluid, gastric aspirates or vomitus, tissue or exudates, and postmortem specimens.
- c. For suspected anthrax exposure, specimens to be submitted depend on the type of exposure and, thus, sample should be collected from the primary site of infection. Cutaneous anthrax would require specimens from the skin; vesicular fluid from fresh vesicles or material from under the edge of the eschar

are necessary. Gastrointestinal anthrax requires abdominal ascites or specimens from stool or rectal swabs. Blood is the best specimen for inhalational anthrax.

- d. Variola virus specimens are highly infectious and should be treated with BSL4 precautions. Variola virus specimens include vesicle, pustule, scab, or fluid from the patient's pox.

11. The first stage in biofilm formation is attachment to a solid surface. This stage is irreversible and is mediated by attachment of molecules and pili. The next stage is characterized by the formation of small cell aggregates and loss of motility. Once the biofilm contains multilayers of cells and has reached a thickness of about 10 μ m, it is in stage III. When the biofilm reaches its maximum thickness, generally about 100 μ m, it is in stage IV. The fifth and final stage begins when cells are dispersed from the biofilm. These cells can presumably establish a biofilm downstream.
12. Biofilms aid microbial attachment because of the production of exopolysaccharide (EPS) by some members of the community and cell-to-cell interactions, resulting in the formation of cell aggregates. The EPS can bind to bacteria of many different species leading to cell aggregate formation.
13. A mature multispecies biofilm will consist of many microcolonies containing different species of microorganisms in several layers. The microcolonies are described as being mushroom-shaped and anchored to the substratum. The microcolonies are surrounded by a matrix consisting of EPS, DNA, and other molecules. Flowing around the microcolonies are water channels that can carry nutrients, DNA, and bacteria.
14. Biofilms can increase antimicrobial tolerance by acting as barriers to penetration. Nutrients, antimicrobial agents, and other molecules may be trapped by the matrix and diffuse slowly; they may not even reach the cells in the lower layers. In addition, because the bacteria near the substratum have fewer nutrients and may be in an anaerobic environment, they are growing slowly, and slow-growing microorganisms are more resistant to antimicrobial agents. Some members of the biofilm can secrete molecules, like penicillinase, that inactivate antimicrobial drugs. Finally, the environment within a biofilm facilitates the exchange of genetic material, and drug-resistant genes can be readily transferred from one organism to another.
15. Virulence mechanisms of biofilms include aiding microbial attachment, increasing the efficiency of

community metabolism, enhancing antimicrobial drug tolerance, protecting against host defenses, facilitating gene transfer, stimulating an inflammatory reaction that damages host tissue, and allowing the spread of microorganisms to other body sites.

16. Indwelling medical devices increase the risk of infection by providing a substrate for microbial attachment. Many microorganisms can readily adhere to hydrophobic plastics and polymers, inducing the formation of a biofilm. Once a biofilm is established, cells can break off and establish an infection downstream.
 17. Areas of concern for clinical microbiologists when dealing with biofilms include false-negative cultures, viable but nonculturable organisms, underestimated colony counts, inappropriate specimen collection, and increased antimicrobial resistance.
 18. One method for studying potential biofilm formation in vitro is based on the staining of microorganisms attached to a solid surface, such as wells of a microtiter plate or the inside of test tubes. The color intensity of the stained cells can be read by a spectrophotometer. Alternatively, bacteria can be allowed to grow in the presence of silicone disks. Growth on the disk is measured by a colorimetric method.
 19. When a biofilm in an individual is disrupted by treatment, bacteria can be released. These bacteria can establish an infection elsewhere in the host. It is important for health care providers to monitor patients after treatment for such an occurrence.
 20. Monoclonal antibodies directed against DNABII proteins might disrupt biofilms. The DNABII proteins are positioned at the vertices of the cross strands of extracellular DNA within the biofilm. Disruption of these proteins results in destabilization of the biofilm causing it to disaggregate.
5. Transmission of SARS-CoV-2 is thought to be primarily through exposure to large droplets, but airborne transmission has also been recognized. Unlike influenza, it was subsequently learned that many infected individuals are asymptomatic, and both asymptomatic and presymptomatic transmission are significant contributors to the spread of infection, making containment particularly challenging.
 6. The common bacterial pathogens that cause community-acquired pneumonia are *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and, increasingly, *Staphylococcus aureus*.
 7. Influenza viruses are constantly changing genetically. The changes can evolve slowly in the population due to mutations caused by the error-prone viral RNA polymerase. This process is termed *antigenic drift*. It is associated with influenza of the same HN phenotype (e.g., H3N2) that has subtle changes in these viral antigens, which can render existing host immunity less effective. In contrast, *antigenic shift* is a term used for a relatively sudden appearance in the global population of an influenza strain that has resulted from genetic recombination (so-called *gene segment reassortment*) among multiple viruses. Whereas genetic drift occurs almost annually, genetic shift is an uncommon epidemiologic event, having occurred only a few times since the 1800s. Antigenic shifts are unpredictable and have the major problem of a much higher transmission rate because of the lack of immunity to these new viruses by most people in the global population. Influenza A can undergo both types of genetic change, whereas influenza B changes mostly by genetic drift.
 8. There is a difference between the groups of pathogens that cause community-acquired and healthcare-associated pneumonias, which makes diagnosis and management different for pneumonias in these two settings. For example, community-acquired pneumonia is more likely to be caused by streptococci, whereas healthcare-associated pneumonia is more likely to be caused by gram-negative bacilli, such as *Pseudomonas*, *Klebsiella*, and *Enterobacter*. The pathogens that cause healthcare-associated pneumonias are more likely to have increased resistance to antimicrobial agents and thus be more difficult to treat.
 9. The absolute CD4 cell count is a surrogate marker for assessing the level of immunosuppression and the risk of HIV-associated complications. When CD4 cell counts are relatively preserved, there is generally no increased risk of opportunistic infections, although these patients remain at increased risk of virulent respiratory infections that also affect the immunocompetent individuals, including tuberculosis and pneumococcal pneumonia. When the CD4⁺ cell count falls, the risk of infection with opportunistic pathogens such as *Pneumocystis jirovecii* increases significantly.
 10. In patients such as the one described here, tuberculosis (TB) should be high on the list of differential diagnoses. Because TB can be a presenting illness in HIV-infected patients, all patients newly diagnosed with active TB should also be tested for HIV infection.
 11. *Bacillus anthracis*, *Yersinia pestis*, and *Francisella tularensis* have been identified as bacterial pathogens that might

Chapter 32

1. The normal microbiota of the respiratory tract plays an important role in protecting the host from infection. Isolation of normal biota from a microbiologic specimen will have less clinical significance than the isolation of pathogenic microorganisms capable of causing disease.
2. Immunocompromised hosts are at risk to develop infection with opportunistic pathogens. These organisms are of low virulence and generally are not pathogenic in hosts with an intact immune system.
3. Opportunistic pathogens are so-named because they generally do not cause disease in normal hosts but require the “opportunity” of an impairment of host defense mechanisms to cause disease.
4. Certain pathogens exhibit seasonal variation and are more common during certain times of the year. Awareness of seasonal trends helps narrow the possible causes of infection, thereby facilitating a more accurate and timely diagnosis. This trend is seen in winter, when there is an increase in viral infections, such as influenza and related postviral bacterial pneumonias, such as those caused by *Streptococcus pneumoniae* and *Staphylococcus aureus*.

be used as agents of bioterrorism and clinically present as severe respiratory infections.

12. The diagnostic microbiology laboratory must be alerted if these agents are suspected in the diagnosis of pneumonia because culture isolation of these microorganisms poses a risk to laboratory personnel and must be performed under conditions of biocontainment.

Chapter 33

1. *Candida* spp. can be part of the normal skin microbiota and can enter the bloodstream when intravenous catheters are in place by adhering to and forming a biofilm on the catheter. In addition, total parenteral nutrition has been associated with the development of candidemia; glucose solutions and lipid emulsions can enhance *Candida* biofilm formation.
2. Folliculitis is an inflammation and infection of hair follicles often caused by *Staphylococcus aureus*. Folliculitis can progress to involve deeper tissues and result in nodules called furuncles, which are red, firm, and can drain pus. Carbuncles are lesions that extend even deeper, into the subcutaneous fat, and are composed of multiple abscesses that coalesce. Carbuncles can be associated with systemic symptoms like fever and bacteremia.
3. Cellulitis in diabetics is often caused by staphylococci or streptococci. Ulcerative lesions and gangrene may also be caused by staphylococci and streptococci but are often mixed infections, including gram-positives, members of the order Enterobacterales, *Pseudomonas*, and anaerobic bacteria including *Clostridium* spp.
4. Zoonotic diseases are those transmitted to humans by wild or domestic animals. There are hundreds of zoonoses, but some of the more common ones that cause skin and soft tissue infection include Rocky Mountain spotted fever (caused by *Rickettsia rickettsii* and transmitted by ticks), leptospirosis, bartonellosis, and tularemia.
5. The most common molds causing skin lesions in this setting are *Fusarium* and *Aspergillus*, opportunistic fungal pathogens that infect immunocompromised persons. They invade blood vessels and cause tissue necrosis. *Fusarium* can be isolated in blood cultures, but *Aspergillus* is only rarely detected this way.
6. Members of the family Herpesviridae are characterized by the establishment of lifelong infection. The initial infection is often accompanied by symptoms, but this is usually followed by a prolonged asymptomatic period, during which the virus latently infects the host. The herpesviruses that are most likely to reactivate in adulthood after a period of latency include varicella-zoster, leading to shingles, and herpes simplex virus, leading to outbreaks of oral or genital ulceration.
7. Swimmer's itch is a very pruritic, papular rash caused by bird or animal schistosomes. They penetrate the skin of humans who bathe or swim in infected waters. These nonhuman schistosomes do not mature in humans, and they die in the skin. *Creeping eruption* or *ground itch* are common terms for the dermatitis known as *cutaneous larva migrans* (CLM). The CLM syndrome is caused by the subcutaneous migration of larvae of animal nematodes such as dog and cat hookworms, *Ancylostoma caninum* and *Ancylostoma braziliense*, respectively. The larvae of these and other worms can penetrate the skin of humans and produce a self-limited, itchy, indurated dermatitis.
8. *Staphylococcus aureus* may produce toxins that cause the exfoliating skin condition known as *staphylococcal scalded skin syndrome*, and toxin production by *S. aureus* or *Streptococcus pyogenes* may produce a diffuse erythroderma associated with toxic shock syndrome. Toxin production by *S. pyogenes* may also result in scarlet fever, characterized by a red, sandpaper-textured rash.
9. Infections caused by *Actinomyces* and *Nocardia* can be characterized by the formation of so-called *sulfur granules*, yellow particles consisting of masses of tangled filamentous bacteria. Microscopic analysis of the granules by staining and by culture can identify the infecting organism.
10. It is important to collect the proper specimen at the correct time in the course of the infectious process. The skin surface should be cleansed to reduce the likelihood of recovering colonizing microbiota not associated with the infection. It is recommended to collect samples from the outer edge of larger lesions. The specimen must be maintained under conditions that preserve the viability of the pathogens. This often includes the use of a transport medium appropriate for the expected pathogens (i.e., bacterial, fungal, or viral).

Chapter 34

1. Gastrointestinal tract host defense mechanisms help prevent pathogens from causing diarrheal illness. The stomach has an acidic environment, with a pH less than 4, which kills more than 99.9% of coliform bacteria within 30 minutes. The small intestine prevents infection through peristalsis. The constant motion prevents bacteria from adhering to the intestinal wall and thus prevents the bacteria from causing infection. The colon and small intestine prevent infection through their normal biota—resident bacteria that normally live in these sites. The normal biota competes with pathogens for nutrients and can also produce toxins to kill pathogenic bacteria. The colon also produces IgA antibody to help fight pathogens.

2. A detailed history and physical examination is often all that is needed to manage acute diarrheal illness. The history should help identify the cause of illness. It should include a detailed dietary history of the 4 to 5 days before symptom onset; contact with individuals with similar symptoms; travel history; recreational activities such as hiking, backpacking, and swimming; and recent antimicrobial use. The symptoms should be well characterized through questions about duration, inflammation, history of previous gastrointestinal symptoms, and any other associated symptoms. One should also ask about other medical illnesses, specifically HIV and cancers, and about all medications that the patient is taking. All this information can help identify the possible causes of diarrhea.
3. Laboratory studies are often not indicated for acute diarrhea because most episodes resolve within 1 day. However, laboratory testing is indicated for those with persistent diarrhea, severe illness, or suspicion of an outbreak. Tests that are usually done include the following: (1) white blood cell count to assess for invasive infection; (2) hemoglobin—anemia can be present with blood loss or hemolytic infection; (3) platelet count; (4) electrolyte panel, which assesses for abnormalities in sodium, potassium, bicarbonate, and creatinine levels as an indicator of hydration status; and (5) fecal leukocyte count to look for evidence of inflammation. If a bacterial infection is suspected, a stool culture is sometimes performed to identify the pathogen.
4. Cytomegalovirus (CMV) is the primary virus that causes diarrhea, often associated with pain, bloody stools, and fever, in immunocompromised patients.
5. An immunocompromised condition can allow a wider range of infectious agents to produce diarrhea. Besides the agents typically found in immunocompetent individuals (bacteria and parasites), the laboratory should screen for mycobacteria, cytomegalovirus, histoplasmosis, and *Strongyloides*.
6. *Entamoeba histolytica* causes fever and grossly bloody diarrhea; however, if the disease is mild, it also can present as watery diarrhea. The trophozoites of *E. histolytica* can leave the intestines and cause metastatic illness, such as a liver abscess.
7. Scombroid is a toxin-mediated illness associated with fish exposure, usually tuna, mackerel, and yellow jack. The tissues of the fish contain histamine and enzyme inhibitors, which cause the symptoms. Symptoms are rapid in onset and include flushing, headache, crampy abdominal pain, and diarrhea. Ciguatera is caused by ciguatera toxin, which is produced by dinoflagellates. Cases of illness are associated with snapper, sea bass, grouper, and barracuda exposure. Symptoms include diarrhea, abdominal pain, weakness, paresthesia, and headache. Other toxin-mediated illnesses associated with fish include paralytic shellfish poisoning (resembling ciguatera) and tetrodotoxin, found in puffer fish, which results in death in more than 50% of patients exposed.
8. Most bacterial diarrheal infections are mild and easily treated with antimicrobial agents; however, rarely, complications can occur. For example, Guillain-Barré syndrome, an ascending paralysis, has been associated with *Campylobacter jejuni* infection. Hemolytic-uremic syndrome is associated with infection with enterohemorrhagic *Escherichia coli* (EHEC) and *Shigella* spp. and is characterized by hemolytic anemia, low platelet count, and kidney failure. Any severe illness can result in death if supportive care is not available; for example, cholera leads to death from dehydration in many developing countries.
9. *Clostridioides difficile* infection is associated with prior antimicrobial use. The use of antimicrobials can suppress the growth of the resident microbiota, favoring the growth of drug-resistant *C. difficile*.
10. *Vibrio cholera* serogroups O1 and O139 have been implicated as causes of epidemic cholera.
11. Traveler's diarrhea is a common problem in patients visiting developing countries; most cases are mild and self-limiting. The most common bacterial cause is enterotoxigenic *Escherichia coli* (ETEC); rotavirus is the most common viral pathogen. Traveler's diarrhea is best avoided by drinking only bottled beverages and avoiding high-risk foods and ice. High-risk foods include any foods prepared by another person and served uncooked (e.g., salad, fruits, vegetables), dips and other foods left standing at room temperature, and raw or partially cooked fish or shellfish.

Chapter 35

1. The cerebrospinal fluid (CSF) is produced by filtration and secretion from specialized capillary tufts of the choroid plexus within the four ventricles of the brain. The CSF flows from the two lateral ventricles to the third ventricle and enters the fourth ventricle via the aqueduct of Sylvius. From there, the CSF enters the basal cisterns and circulates over the cerebellum and convexities of the cerebral hemispheres. The CSF is absorbed primarily by the arachnoid villi through tight junctions of their endothelium.
2. CSF is a clear, colorless, and sterile fluid. In healthy adults, the protein level is 20 to 60 mg/dL, and the glucose level is 40 to 80 mg/dL (CSF glucose-to-serum glucose ratio of 0.6). Normally, few white blood cells are present.
3. The common bacteria causing acute meningitis include *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Streptococcus agalactiae* (group B *Streptococcus*), *Haemophilus influenzae*, and *Listeria monocytogenes*. Patients with sickle cell anemia, splenectomy or asplenia, malignancy, malnutrition, and chronic renal or liver disease are more likely to develop serious *S. pneumoniae* infection. Individuals who are deficient in terminal components of complement (C5 to C9) or

properdin are at higher risk for *N. meningitidis* infection. *S. agalactiae* is a common cause of meningitis in neonates and infants up to 3 months of age. *Escherichia coli* is a less common cause of infection in this population. Neonatal acquisition usually results from vertical transmission from mother to infant. Before the widespread use of a conjugated vaccine, *H. influenzae* was a common cause of invasive illness in young children. The incidence of invasive disease by this organism has been substantially reduced. Infection caused by *L. monocytogenes* is more commonly seen in neonates, older patients, alcoholics, and immunosuppressed individuals.

4. In acute bacterial meningitis, the CSF is turbid because protein levels and white blood cell counts are significantly raised. Primarily, the neutrophils are increased in number. Glucose levels are very low (<40% of the serum glucose concentration) in most patients with bacterial meningitis. In viral infections, the number of lymphocytes is increased in the CSF, and protein concentrations are slightly elevated, whereas the glucose concentration is near the reference range. Fungal and tuberculous meningitis is characterized by increased lymphocytes and elevated protein and decreased glucose levels.
5. *Candida* spp., *Aspergillus* spp., *Mucor*, *Rhizopus*, and *Absidia* are the common fungi that can cause brain abscesses. *Blastomyces dermatitidis* is also associated with abscesses.
6. *Cryptococcus neoformans/gattii*, *Coccidioides immitis*, *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Candida* spp. are fungal agents associated with meningitis.
7. CSF specimens should be examined as soon as they are received because some of the infectious agents are fastidious and can become nonviable if specimens are not processed quickly. In addition, some infectious agents found in CSF can be diagnosed by rapid assays, facilitating proper treatment of life-threatening infection.
8. Initial examination of a CSF specimen includes a macroscopic description (i.e., turbidity) and microscopic examination of Gram-stained smear. Many laboratories will also perform an antigen detection assay for *C. neoformans*. Antigen detection assays for bacterial meningitis have low sensitivities and are generally not recommended. Nucleic acid amplification tests have been developed for many bacterial agents and have demonstrated improved sensitivity.
9. Sheep blood and chocolate agar media incubated in 3% to 5% CO₂ at 35° C are generally used for bacterial culture of CSF.
10. Tests performed on CSF for the diagnosis of infectious agents include blood chemistry (protein and glucose), cell counts and white blood cell differential, direct antigen detection for *Cryptococcus*, polymerase chain reaction assays, and cultures for bacteria, fungi, and occasionally viruses. In addition, it is sometimes relevant to test for antibodies to common pathogens found in the central nervous system.

Chapter 36

1. The patient had an indwelling catheter, which was likely the source of infection. Because it was an endovascular source, however, it is considered a primary bacteremia.
2. The patient has granulocytopenia, which placed him at risk for all types of bacterial infections—in particular, bacteremia. Gram-positive organisms are currently the most common causes of bacteremias in the United States.
3. The following conditions also place patients at an increased risk for bacteremia: reduced immune competency, increased use of invasive procedures and instrumentation, very young or very old age, trauma, and administration of immunosuppressive therapy and other drugs.
4. Sources of bacteremic spread include peritoneal dialysis, pericarditis, bacterial pneumonia, bed sores, prosthetic devices and instrumentation, and skeletal, skin, and soft tissue infections.
5. Common bacteria present in pneumonias that produce a concurrent bacteremia include *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Pseudomonas aeruginosa*, and *Enterobacter/Klebsiella* spp.
6. Sepsis, septic shock, renal failure, and eventually death are major consequences of septicemia.
7. Antimicrobials, antisepsis therapy, physiologic support (monitor intravascular volume and blood pressure), and anticoagulation agents have been used as treatment for sepsis.
8. Those at risk for polymicrobial bacteremia include immunocompromised patients, especially those with alcoholism, granulocytopenia, extensive burns, diabetes mellitus, and renal failure. Patients with vascular insufficiency resulting from ischemia are also at risk.
9. It is recommended that 10 mL of blood should be drawn from adult patients and placed in 90 mL of liquid medium (1:10 dilution) in each blood culture bottle of a set. This ratio helps reduce the bactericidal effect of serum. Sodium polyanetholsulfonate (SPS) in the culture medium serves as an anticomplement and anticoagulant.
10. The number of samples and time of collection could be highly dependent on the type of bacteremia suspected. In general, collecting three sets of blood cultures within a 24-hour period at 1-hour intervals is appropriate, especially in suspected cases of subacute endocarditis.

4. c
5. b
6. c
7. d
8. c
9. d
10. b

11. Urine would be collected, likely by clean catch, midstream and plated onto sheep blood agar and a medium selective for gram-negative bacilli, such as MacConkey agar. Plates would be placed at 35° C for at least 16 hours and observed for growth of a predominant organism. After the organism is isolated, it would be identified and antimicrobial susceptibility testing performed.
12. The patient showed signs of a UTI and sepsis. The organism was identified as *Staphylococcus aureus* and was likely spread via the hematogenous route—through the bloodstream. The most common route of infection is through the ascending route, where organisms are introduced via the patient's fecal or skin biota into the urethra.
13. The patient's deteriorating symptoms (delirium, hypotension, fever) in addition to laboratory findings of leukocytosis and positive urine and blood cultures signify urosepsis. The patient should be treated aggressively with empiric antimicrobials until susceptibility results of the blood and urine cultures are completed.
14. A single-episode UTI occurs only once and resolves after antimicrobial therapy, whereas recurrent UTIs occur repeatedly. Recurrent UTIs may involve the same organism (relapse) or a different organism (reinfection).
15. A rapid enzymatic assay, referred to as a *urine dipstick*, is used for initial screening. If reactions indicating the presence of red blood cells, white blood cells (by leukocyte esterase), and/or nitrates are present, the urine then undergoes a microscopic analysis. If the microscopic analysis confirms the presence of white blood cells (pyuria) and bacteria (bacteriuria), or yeasts, cultures are performed. A diagnostic algorithm is useful so only urine samples with a high probability of microbial growth are cultured, which saves cost and laboratory time and gives the clinician insight in determining whether or not the patient has a true UTI to help guide the treatment plan.
16. The minimum incubation time is 16 hours, but the optimal time is 24 hours at 35° C.
17. With longer incubation times, overgrowth of normal biota can obscure a true pathogen. This can result in time lost as additional days are needed to separate normal microbiota from pathogens, and the clinical relevance of the urine culture becomes more confusing.
18. Specimens with multiple species (three or more) likely represent contamination.
19. Routine urine cultures do not include the recovery of fastidious organisms, such as *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, or *Ureaplasma urealyticum*. Symptoms produced by these organisms are difficult to differentiate from those of a true UTI.
20. Sexually active females have a higher rate of *Staphylococcus saprophyticus* infection than other populations. Anyone who is sexually active is also at risk for an STI causing UTI symptoms. A middle-aged man would most likely have common gram-negative pathogens, such as *Escherichia coli*, *Klebsiella* spp., and *Enterobacter* spp. An elderly woman could have yeast present, *Gardnerella vaginalis*, and, if catheterized, possibly *Pseudomonas* spp. and *Proteus* spp. A renal transplant patient can have BK, JC, or adenoviral infections that can present like bacterial infections.
21. The presence of dysuria suggests a UTI while fever, chills, nausea, and vomiting indicate possible sepsis. The UTI could be attributed to hematogenous spread of the infectious agent. The patient's history of a recent organ transplant and likely immunosuppressive therapy places this patient at risk for sepsis. A urinalysis and urine and blood cultures should be performed.

Chapter 38

1. Pelvic inflammatory disease (PID) relates to several different syndromes affecting the uterus, fallopian tubes, and other reproductive organs. PID presents with several vague symptoms, ranging from mild to severe, therefore infection may not be recognized until late in the disease process. The most common complaint is lower abdominal pain, but other potential signs and symptoms include fever, unusual vaginal discharge, painful intercourse, painful urination, or irregular menstrual bleeding. PID can damage the fallopian tubes and tissues in and near the uterus and ovaries while leading to serious consequences, including infertility, ectopic pregnancy, abscess formation, and chronic pelvic pain.
2. There are two common causes of vulvovaginitis: yeast infection (candidiasis) and parasitic infection (trichomoniasis). Women with candidiasis typically present with pruritus (itchiness), although they may also describe painful intercourse and soreness. They have a moderate amount of clumped, adherent discharge (cottage cheese consistency) with no odor. Microscopy performed on a discharge specimen will show budding yeast or fungal elements on the saline wet preparation and the 10% KOH preparation. Women with trichomoniasis may describe soreness and painful intercourse. The discharge is profuse, with a greenish-yellow color and frothy appearance. Application of KOH to this discharge will also produce a fishy smell. Microscopic examination of the discharge can confirm the disease by viewing motile trichomonads in the saline wet mount, but nothing significant is visible in the KOH preparation. Bacterial vaginosis (BV), a polymicrobial infection associated primarily with anaerobic bacteria, is not a true inflammation. Women with BV may have some slight abdominal pain, with a moderate white or gray discharge. By applying KOH to the discharge, a distinctive odor (fishy smell) is noticeable because of the increased vaginal pH. On microscopy, the saline wet preparation will demonstrate clue cells, whereas nothing significant is visible with the KOH preparation. Women with trichomoniasis may describe soreness and painful intercourse. The discharge is profuse, with a greenish-yellow color and frothy appearance. Application of KOH to this discharge will also produce a fishy smell. Microscopic examination of the discharge can confirm the disease by viewing motile trichomonads in the saline wet mount, but nothing significant is visible in the KOH preparation.
3. Tracing of sexual contacts notifies those individuals who may be at risk, with the intent of screening them for STIs as well. In this manner, potentially infected

individuals who are asymptomatic can receive treatment much earlier and reduce the overall complications of a delayed or untreated infection. In addition, treatment of asymptomatic carriers might reduce the spread of the infection.

4. Because STIs are transmitted in the same manner, individuals diagnosed with a specific STI are at risk of infection with another STI. Testing for other STIs should be based on specific risk factors of the individual. However, at a minimum, all diagnosed patients should also be tested for HIV infection.
5. Because of the serious emotional consequences of informing a patient that they have an STI, it is imperative to ensure that laboratory results are confirmed. The most common STIs requiring a confirmatory test are syphilis and HIV infection. Syphilis testing uses a nontreponemal (nonspecific) antibody test such as the rapid plasma reagin test because of its high sensitivity, followed by a treponemal antibody test such as the *Treponema pallidum* particle agglutination test, which is very specific. Infection with HIV is initially screened by an HIV-specific ELISA assay for HIV-1/HIV-2 antibody and p24 antigen. An initial HIV ELISA reactive result should be repeated by an HIV-1/HIV-2 antibody differentiation immunoassay.
6. A variety of preventive measures can help to reduce the spread of STIs. Educating people at greatest risk of developing infection helps them to make better decisions concerning their sexual activities and social interaction. Also, once diagnosed, community and public health officials are notified to help identify and locate all sexual contacts of the individual to get them tested as well. Public health officials also promote safe sexual practices by recommendations such as using protective barriers, prophylaxis, and changing lifestyle habits, such as serosorting, in which HIV-positive individuals only have sexual relations with other HIV-positive individuals.
7. There are two main differences of clinical presentation. Chancres are typically painless, so the individual may not even be aware that he or she is infected. Such lesions are firm and singular in nature, with a sharp demarcated border and a red smooth base. Chancroids are often soft, painful lesions that may appear singly or in groups of three, with an erythematous border and a yellow gray base.
8. Molecular testing has vastly increased the sensitivity and specificity of detection in comparison with culture and a much faster turnaround time for results. Different targets of amplification have been developed to identify other disease agents that may have been difficult to detect before.
9. The symptoms of urethritis are similar, whether caused by *Neisseria gonorrhoeae* or *Chlamydia trachomatis*. In either case, there is urethral inflammation, dysuria, and a discharge. Infected males are typically symptomatic, whereas many females remain asymptomatic. The main discriminating factor is the appearance of the discharge. Gonococcal infections generally yield a purulent discharge; nongonococcal infections may demonstrate a cloudy or watery discharge. The discharge from symptomatic males can be Gram stained. Specimens that show many white blood cells and intracellular gram-negative diplococci provide strong evidence of gonococcal diagnosis because no diplococci are present in the nongonococcal form. However, there are saprophytic *Neisseria* spp. in the female genital tract that might give a similar Gram stain result.
10. Over 150 genotypes of HPV are known, but only 9 of them are included in the vaccine. There are two main groups of genotypes: low risk (e.g., types 6 and 11) and 14 high risk genotypes (e.g., types 16, 18, 31, 33, and 45) for developing cancer. This vaccine protects against nine HPV types: 6, 11, 16, 18, 31, 33, 45, 52, and 58. Since 2016, this has been the only HPV vaccine available in the United States.
11. Patients with HIV infection may also be infected with another STI and should be screened appropriately, depending on their individual risk factors. Screening for tuberculosis is also important because a dual infection speeds up the development of AIDS. Newly confirmed infected patients should have HIV viral load and CD4⁺ count tests performed to establish a baseline of the patient's status, which can be compared with future results to determine the efficacy of treatment.
12. Both of these viruses are considered bloodborne pathogens, but they can be spread by many different mechanisms. Hepatitis B virus is spread via contact with blood, semen, vaginal secretions, and other body fluids of an infected individual. Sexual transmission is responsible for nearly 50% of all HBV infections in the United States. Hepatitis C virus is spread through contact with an infected person's blood and through sexual transmission. Therefore when patients are confirmed to have an STI, they may also require screening for HBV and HCV, depending on their risk factors.
13. All of the herpesviruses have the capability to establish a latent infection. Following productive infection by HSV at the site of inoculation, the virus spreads to and enters sensory neurons, forming a reservoir of virus for recurrent infection, disease, and transmission to other individuals. Reactivation of the virus from the latent state is caused by several triggers, most of which are stress-related. As the virus travels along the nerve axon, lesions occur at the dermatome, which is the area of skin innervated by a single posterior spinal nerve. Thus recurrence of infection occurs at the same site as the initial infection.
14. The declining rate of syphilis was most likely related to the epidemic of HIV infections that encouraged individuals to practice safe sex. Now that many of the younger generation see famous infected individuals who appear healthy, they feel as though HIV can be cured in their lifetime. This attitude has led to increasingly high-risk sexual behaviors.
15. The increasing level of resistance may lead to greater spread of the disease and a reduction in the number of alternatives for treatment. Molecular testing has replaced culture techniques because of increased sensitivity and specificity, ease of testing, multiple specimen types, and rapid turnaround time. Once an individual was diagnosed, the patient would usually respond to antimicrobial therapy. Now, with increasing drug resistance, the only way to detect such isolates

would be to recognize that a patient has failed therapy, and therefore actual culture and susceptibility testing will be required. This extends the period of testing before identifying the appropriate therapy and potential for long-term complications, especially if a patient does not return for follow-up care.

Chapter 39

1. The splenectomy that the patient underwent following the traffic accident placed her at an increased risk for infection, particularly from encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*.
2. Malignancy can cause deficiencies in both humoral and cellular immunity. Tumor cells can destroy the normal function of certain cell types in the body, or they may produce cytokines that cause immunosuppression. Cytotoxic drugs given to patients with malignancy can break down mucosal barriers and impair immune response.
3. Although a decrease in the number of neutrophils is the most common hematologic disturbance, inadequacy of neutrophil function, such as the inability to migrate to sites of inflammation, is another cause of increased infections among such patients. The inability of neutrophils to phagocytize or kill ingested organisms also predisposes patients to infection and places them at risk of infection from endogenous organisms.
4. Many organisms are of concern in women who are pregnant. *Escherichia coli* and other gram-negative bacilli can cause urinary tract infections, and *Candida* spp. can cause vaginal yeast infections. Several organisms can cause congenital infections, including *Toxoplasma gondii*, rubella virus, cytomegalovirus, herpes simplex virus, varicella zoster virus, HIV, parvovirus B19, hepatitis B virus, *Treponema pallidum*, *Streptococcus agalactiae*, and *Listeria monocytogenes*. Several organisms can be transmitted during labor and delivery and may adversely affect the baby, including *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *S. agalactiae*, *Escherichia coli*, human papillomavirus, cytomegalovirus, and herpes simplex virus.
5. Several changes in immune function occur as the body ages, increasing its susceptibility to infections and malignancy. The qualitative decline of cellular immune defenses (function) predisposes older individuals to various types of infections, including respiratory, gastrointestinal, urinary tract, and soft tissue infections. Because of decreased tumor surveillance by immune and nonimmune mechanisms, the occurrence of malignancy in this population is also increased.
6. Organisms associated with causing infection in patients with cystic fibrosis include *Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Haemophilus influenzae*, *Burkholderia cepacia*, and *Aspergillus fumigatus*. Organisms associated with causing infection in patients with ventilator-associated pneumonia include *Streptococcus pneumoniae* and other streptococci, *H. influenzae*, *S. aureus*, *P. aeruginosa*, *Klebsiella*, *Enterobacter*, *Serratia*, *Acinetobacter*, *Stenotrophomonas*, and *B. cepacia*.

7. Chemotherapy and radiation therapy adversely affect the immune response by damaging white blood cells. These cells are involved in phagocytosis, humoral-mediated immunity, and cell-mediated immunity.
8. b
9. d
10. a

Chapter 40

1. Lyme borreliosis, or Lyme disease, is associated with erythema migrans. *Borrelia burgdorferi* is the causative agent of erythema migrans.
2. Relapsing arthritis of large joints, including the knees, shoulders, and elbows, is the most common clinical manifestation of late, persistent Lyme borreliosis.
3. Cats and dogs are the two animals most often associated with pasteurellosis. *Pasteurella multocida* can be found as normal biota in the oral cavity of these animals.
4. Patients who have been splenectomized or are suffering from cancer are at increased risk. Intravenous drug users may be at increased risk as well.
5. *Bartonella henselae* is the primary causative agent of cat scratch disease. A small number of cases may also be associated with *Bartonella clarridgeiae* and *Bartonella quintana*.
6. Protective antigen (PA) and edema factor (EF) are responsible for the life-threatening edema in pulmonary anthrax. PA must bind with EF to make it biologically active and serves as a transport protein to carry EF into the host cell. EF is an adenylate cyclase that causes edema.
7. The four species are *Brucella melitensis* (goats), *Brucella abortus* (cattle), *Brucella canis* (canines), and *Brucella suis* (swine).
8. Anicteric leptospirosis is the milder, less lethal form of the disease, which is typically biphasic. The characteristic symptom for this disease is pink eyes. Icteric is much more likely to be life threatening, with a mortality rate of 15% to 40%. Although this form may initially present similarly to the anicteric form, on about the third day the patient begins showing signs of hemolysis, jaundice, and renal failure as the leptospire multiplies in the liver and kidney.
9. *Anaplasma phagocytophilum* and *Ehrlichia chaffeensis* are the causative agents of HGA and HME, respectively. The severity of these infections is increased in patients with impaired splenic function or those with a history of splenectomy.
10. The typhus group includes *Rickettsia typhi* and *R. prowazekii*.
11. Rocky Mountain spotted fever is the most severe of the rickettsial infections. By infecting endothelial cells, the organism causes vascular damage to the internal organs, including the brain, heart, lungs, and kidneys.
12. Emerging zoonotic diseases can jump from animals to humans. They can be newly discovered agents, known disease agents that have moved to a new geographic location, or known diseases that have undergone a mutation, making them more pathogenic (e.g., increased drug resistance). The cost associated with zoonotic

outbreaks in the past decade has been estimated at \$200 billion. Massive economic loss has also been associated with the COVID-19 pandemic that started in 2019 and is still ongoing.

6. Specimens from the conjunctiva are the most commonly submitted specimens from ocular sites. The most frequent isolates are *Staphylococcus aureus*, coagulase-negative staphylococci, *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Pseudomonas aeruginosa*.
7. Gram, Giemsa, calcofluor white, acid-fast, and immunofluorescent stains are commonly used on ocular material.
8. The topical route is the most common route of administering antimicrobial agents in the treatment of eye infections. In more serious infections, systemic treatment may be required.
9. *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and herpes simplex viruses are sexually transmitted agents that can also affect the eyes.
10. Corneal scraping material collected by an ophthalmologist should be plated directly to culture media and used to make a smear. Plates and slides should be transported immediately to the laboratory.
11. Soft lenses contain a large percentage of water, allowing pathogens to survive and multiply. Improper handling of lenses (i.e., poor hygiene) and failure to follow the manufacturer's recommended procedures on how to keep lenses, lens solutions, and cases from being contaminated place the lens wearer at risk for eye infection. Proper handwashing and good hygiene practices to prevent lens contamination may reduce the risk. Avoid wearing contact lenses in water.

Selected bacteriologic culture media

Connie R. Mahon and Donald C. Lehman

A wide variety of basal, enrichment, selective, and differential media are available to the clinical microbiology laboratory. Each of these media is intended to aid the laboratory scientist in the isolation, cultivation, and identification of clinically significant organisms from patient specimens. Efficient laboratory performance depends not on maintaining a vast array of media for routine use, but on the ability to make wise choices when selecting a routine media menu—choices that should be dictated by the factors discussed in [Chapter 6](#). This appendix provides information about a select number of bacteriologic media cited in the bacteriology sections of this text. Most media detailed in this appendix are commercially available as a dehydrated powder or in ready-to-use form. Sterility and performance tests (quality controls) should be performed, as discussed in [Chapter 5](#).

Alkaline peptone water

Alkaline peptone water is an enrichment medium useful in the recovery of *Vibrio* and *Aeromonas* spp. from stool specimens. The alkaline pH of this medium allows uninhibited replication of these species while temporarily suppressing the replication of many commensal intestinal bacteria. The sodium chloride (NaCl) concentration is 1%.

Some formulations recommend adjusting to pH 9.0 and adding NaCl to a concentration of 3% (alkaline peptone salt broth) to specifically recover the vibrios. Alkaline peptone water cultures should be incubated at 35°C and subcultured to thiosulfate citrate bile salt sucrose (TCBS) agar within 12 to 18 hours.

American Trudeau Society medium

American Trudeau Society (ATS) medium is an egg-based medium used for the isolation of mycobacteria, particularly *Mycobacterium tuberculosis*, from clinical specimens. The eggs provide fatty acids, and potatoes are included to provide

a carbon source. Malachite green is incorporated into the medium, which is slightly inhibitory for bacteria that are part of the normal microbiota.

Amies transport with and without charcoal

Amies transport medium, a modification of the Stuart transport medium, is commonly used to maintain the integrity of the specimen from the time of collection until laboratory processing of the sample. This medium usually contains substances that do not promote multiplication of microorganisms but ensure their preservation. Swab collection systems may contain this medium. Amies transport medium may contain charcoal that absorbs fatty acids given off by the swab or present in clinical specimens that can be detrimental to the survival of *Neisseria gonorrhoeae* and *Bordetella pertussis*. The medium contains 0.3% NaCl for optimal preservation of *N. gonorrhoeae*. Potassium, calcium, and magnesium salts control permeability of bacterial cells by maintaining osmotic equilibrium while phosphate buffer maintains the pH of the medium.

Bacteroides bile esculin agar

Bacteroides bile esculin (BBE) agar is a selective differential agar used for the isolation and identification of members of the *Bacteroides fragilis* group. The incorporation of oxgall (bile salts) separates bile-resistant species (growth) from bile-sensitive ones (no growth), whereas the 1% esculin, in conjunction with ferric ammonium citrate, differentiates between the isolates that grow based on the isolate's ability (positive) or inability (negative) to hydrolyze esculin. If the organism produces esculinase, it will hydrolyze esculin into esculetin and glucose and metabolize the glucose. Esculetin reacts with the ferric ammonium citrate to form an insoluble iron salt in the medium surrounding the positive colonies, causing it to turn

dark brown or black. Plated medium should be inoculated, streaked for isolation, and incubated anaerobically at 35°C.

Bile esculin agar

Bile esculin agar is a selective differential agar used to isolate and identify group D streptococci and the enterococci. Oxgall (bile salt) is the selective ingredient that inhibits the growth of most gram-positive organisms, whereas esculin is the differential component. All group D streptococci and enterococci can grow in the presence of bile and hydrolyze esculin. Products of esculin hydrolysis (esculetin) react with ferric citrate in the medium to produce insoluble iron salts. Deposition of the iron salts results in a blackening of the medium. Test results must be interpreted in conjunction with Gram stain morphology because *Listeria monocytogenes* and a small number of other organisms also produce positive reactions.

The addition of vancomycin to the traditional bile esculin medium can be used to detect vancomycin-resistant streptococci and enterococci. Azide is added to some formulations to inhibit gram-negative organisms. When azide is added, the concentration of bile is decreased to make the medium less inhibitory to non-group D streptococci. Bile esculin medium should be inoculated, incubated aerobically at 35°C, and observed for growth. Darkening of the medium indicates esculin hydrolysis.

Bismuth sulfite agar

Bismuth sulfite agar is a selective medium for the isolation of *Salmonella* spp. The selective ingredients are bismuth sulfite and brilliant green, which inhibit the growth of gram-positive bacteria, most lactose-fermenting intestinal normal microbiota (coliforms), and *Shigella* spp. (other than *S. flexneri* and *S. sonnei*). Although this is not a differential medium in the strictest sense, the ferrous sulfate in this medium is reactive with hydrogen sulfide (H₂S) to produce ferric sulfide, which is deposited in the bacterial colony as a black, insoluble precipitate. Typically, *Salmonella* serotype Typhi colonies are black and surrounded by a metallic sheen, whereas *Salmonella* serotype Gallinarum, *Salmonella* serotype Choleraesuis, and *Salmonella* serotype Paratyphi colonies are light green on this medium. When bismuth sulfite agar is used to isolate *Salmonella* from feces and other clinical specimens, the parallel use of a less inhibitory medium is recommended, because bismuth sulfite agar can inhibit or partially inhibit the growth of some *Salmonella* strains.

This medium cannot be autoclaved and must be used on the day it is prepared. Plated medium should be inoculated with fecal or enrichment broth materials, streaked for isolation, and incubated at 35°C for 48 hours.

Blood agar, anaerobic, CDC

The Centers for Disease Control and Prevention (CDC) anaerobic blood agar (CDC, Atlanta, GA) is an enriched medium useful for the isolation of fastidious anaerobes. It is better for the isolation of anaerobic gram-positive cocci than for other

anaerobes. It has a tryptic soy agar base and contains yeast extract, L-cysteine, hemin (factor X), 5% sheep blood, and vitamin K₁. This medium can be stored for up to 6 weeks if sealed in a cellophane bag and stored at 4°C. Plates should be inoculated, streaked for isolation, and incubated anaerobically at 35°C for 48 hours.

Blood agar, anaerobic, with kanamycin and vancomycin

Kanamycin and vancomycin (KV) blood agar is a variation of CDC anaerobic blood agar made semi-selective by the addition of the antimicrobials kanamycin and vancomycin. It is useful in the primary isolation of obligate gram-negative anaerobes, particularly *Bacteroides* spp., from specimens with a mixed bacterial population.

KV blood agar plates sealed in bags can be stored at 4°C for up to 4 weeks. Plates should be inoculated, streaked for isolation, and incubated anaerobically at 35°C for 48 hours. Inoculated plates that lack growth at 48 hours may be re-inoculated, depending on the situation.

Blood agar, rabbit

Rabbit blood agar is an enrichment medium particularly useful in the recovery and the demonstration of β-hemolysis by *Haemophilus* spp. and *Gardnerella vaginalis*.

Blood agar, sheep

Sheep blood agar (SBA) is a routine medium used to cultivate a wide variety of moderately fastidious bacteria. An infusion agar, tryptic soy agar base, or Columbia agar base is enriched by the addition of 5% to 10% defibrinated sheep, rabbit, or human blood. Sheep blood, however, has proven to be the most versatile enrichment additive. Incorporation of the blood not only provides enrichment for the growth of bacteria but it also allows for differentiation based on the detection and characterization of hemolytic activity. Plates should be inoculated, streaked, and incubated as dictated by the specific application.

Bordet-Gengou blood agar

Bordet-Gengou (B-G) blood agar is a selective enrichment medium for the isolation of *Bordetella pertussis* and *Bordetella parapertussis* from clinical specimens. Peptone is used in the base medium and is enriched by the addition of glycerol; potato infusion; and sterile, defibrinated sheep blood. Selectivity of the medium is achieved by adding penicillin, methicillin, or cephalixin to the medium.

The antibiotics should be added aseptically just before the addition of the blood enrichment. Blood enrichment of between 15% and 30% is appropriate. The source of the sterile defibrinated blood obtained is not critical, but properly prepared plates should be cherry red, moist, and bubble-free. Complete plated medium should be used immediately if

possible. If this is not possible, plates can be maintained for about 1 week at 4°C if they are tightly sealed.

The medium can be inoculated by rolling the nasopharyngeal swab specimen over one third of the plate surface and then streaking for isolation with a loop. The specimen should be inoculated in this fashion onto B-G plates with and without antimicrobial agents. Inoculated plates should be incubated at 35°C with 5% to 10% carbon dioxide (CO₂) and increased humidity and then examined at 48 hours. Plates that have no growth at 48 hours should be reincubated. Plates must be held for 5 days, but not more than 7 days, before they can be regarded as negative for the organism.

Brain-heart infusion broth

Brain-heart infusion (BHI) broth is an enriched medium suitable for the cultivation of nonfastidious and moderately fastidious microorganisms. This broth medium is recommended for the cultivation of pneumococci for the bile solubility test. Brains and beef heart provide nutrients, and peptones, glucose, NaCl, and buffers also are added. This formulation is used as a blood culture medium. NaCl (6.5%) can be added to differentiate the salt-tolerant enterococci from the streptococci that are inhibited by the high salt concentration. This broth also can be used to prepare inocula for antimicrobial susceptibility testing and detecting vancomycin-resistant enterococci.

Brucella laked sheep blood agar, anaerobic, with kanamycin, vancomycin, and vitamin K

Anaerobic, laked sheep blood agar with kanamycin, vancomycin, and vitamin K (KVKL) is a selective enrichment medium recommended for the isolation of *Bacteroides* and *Prevotella* species from clinical specimens. This medium is particularly helpful in the isolation of *Prevotella melaninogenica* because pigment production is enhanced. Laked erythrocytes (lysed by freezing) and vitamin K constitute the enrichment ingredients; the antibiotics inhibit all cocci and facultative gram-negative bacilli, except the pseudomonads. Other microorganisms can also grow such as some yeast; therefore a Gram stain should always be performed to help differentiate isolates. Plated medium should be inoculated, streaked for isolation, and incubated anaerobically at 35°C for a minimum of 48 hours.

Buffered charcoal yeast extract agar

Buffered charcoal yeast extract (BCYE) agar is an enrichment medium useful in the isolation of *Legionella* spp. from clinical specimens. Ferric pyrophosphate provides iron that is required by the organism. Yeast extract, α -ketoglutarate, and L-cysteine enhance the growth of *Legionella* and other organisms. Activated charcoal is incorporated to absorb toxic compounds that accumulate because of the organism's metabolism or are present following preparation of this

medium. This medium can also be used to isolate *Francisella* and *Nocardia* spp.

Plated media can be stored in plastic bags, away from light, at 4°C for up to 4 weeks. Plated media should be inoculated, streaked for isolation, and incubated at 35°C in a CO₂ incubator. Cultures should be checked daily for up to 2 weeks, and incubator humidity should be monitored to prevent excessive drying of plates. *Legionella* colonies may not be grossly visible until 3 to 5 days after inoculation.

Several modifications of BCYE exist. In one formulation, L-cysteine is omitted. Because *Legionella* spp. require L-cysteine, they will not grow on this medium. Comparison of growth on this L-cysteine-deficient medium with that on regular BCYE can help determine whether an isolate is *Legionella* spp. or another type of gram-negative rod. The addition of antimicrobial agents to BCYE makes the medium selective. Commonly used antimicrobials include cefamandole or vancomycin to inhibit gram-positive organisms; colistin or polymyxin B to inhibit gram-negative bacilli, especially pseudomonads; and anisomycin for fungal inhibition. The Wadowsky-Yee modification uses glycine and polymyxin B to inhibit gram-negative organisms, vancomycin to inhibit gram-positive cocci, and anisomycin to inhibit fungi. This medium is useful in recovering *Legionella* spp. from body sites that contain mixed microbiota. The Wadowsky-Yee modified BCYE also has bromocresol purple and bromothymol blue, which help differentiate among colonies. *L. pneumophila* colonies are light blue, with a pale green tint.

Burkholderia cepacia agar

Burkholderia cepacia agar was developed to isolate *B. cepacia* selectively from respiratory specimens collected from patients with cystic fibrosis. The medium was originally named *Pseudomonas cepacia* agar, which corresponds to the former name of the bacterium. *B. cepacia* grows more slowly than other bacteria and has variable colony morphologies on routine media. As a result, other organisms often overgrow *B. cepacia*, and isolation and detection of *B. cepacia* were problematic. Crystal violet, bile salts, polymyxin B, and ticarcillin are incorporated to inhibit most gram-positive and gram-negative organisms. The medium contains inorganic salts, peptones, pyruvate, and phenol red. *B. cepacia* can grow on this medium and use pyruvate as a carbon source. The breakdown of pyruvate results in the production of alkaline byproducts. The increased pH changes the phenol red indicator from dull yellow to hot pink.

Burkholderia cepacia selective agar

Burkholderia cepacia selective agar (BCSA) is used to select for the isolation of *B. cepacia* in respiratory specimens taken from patients with cystic fibrosis. The base consists of trypticase peptone, yeast extract, sucrose, lactose, and NaCl. Polymyxin B, gentamicin, vancomycin, and crystal violet are the selective agents. *B. cepacia* has variable colony morphology on this medium, from smooth to rough, dry or moist, or purple because of the absorption of crystal violet. In addition, colonies may have a surrounding yellow zone because of carbohydrate fermentation or a pink zone because of peptone

breakdown. BCSA is better for selectively isolating *B. cepacia* than *B. cepacia* agar or oxidative-fermentative base, polymyxin B, bacitracin, lactose (OFBBL) media. This medium can also be used for the isolation of rapidly growing mycobacteria. Inoculated BCSA plates should be incubated aerobically at 35°C and checked every 24 hours for growth. Plates should be incubated for at least 72 hours before they are discarded if there is no growth.

Cary-Blair transport medium

Cary-Blair transport medium is a semi-solid medium designed to preserve and transport clinical samples especially stool and rectal swabs. Its purpose is to enhance the survival and recovery of bacterial enteric pathogens. The low nutrient content in the medium and sodium thioglycolate to inhibit oxidation prevent bacterial multiplication while still maintaining viability and prevent colon biota overgrowth of enteric pathogens. Disodium phosphate is included as a buffering agent, and NaCl is added to maintain proper osmotic pressure. The alkaline pH reduces the damage to bacterial cells when acid is produced.

Campylobacter blood agar

Campylobacter blood agar (Campy-BA) is a selective enrichment medium useful in the isolation and cultivation of *Campylobacter* spp. from stool specimens. *Brucella* agar serves as the base medium for Campy-BA because it contains sodium bisulfite, which lowers the redox potential, thereby enhancing the recovery of microaerophilic organisms such as *Campylobacter* spp. Ten percent sheep blood enriches the basal medium, and an antimicrobial mixture makes the medium selective. Although minor variations exist in the composition of the antimicrobial mixture, most formulations have incorporated vancomycin to inhibit gram-positive cocci, trimethoprim to inhibit swarming strains of *Proteus*, polymyxin B to inhibit gram-negative bacilli, and amphotericin B to inhibit filamentous fungi and yeasts. Cefoperazone is being promoted to replace cephalothin. Cefoperazone has antipseudomonal activity (lacking in cephalothin) and is more effective against members of the order Enterobacterales. After inoculation with stool, the medium should be incubated in a microaerophilic and capnophilic environment at 42°C. *Campylobacter* species generally grow as flat, gray, nonhemolytic colonies, or they may be raised and mucoid. Some isolates may be tan or slightly pink. The colonies may appear swarming or spreading across the surface of the plate.

Campylobacter charcoal differential agar

Campylobacter charcoal differential agar is less inhibitory for *Campylobacter* spp. than other selective media used to isolate *Campylobacter* and is also more inhibitory for organisms found as normal fecal microbiota. Preston agar is the base that is supplemented with beef extract and peptones. Cefoperazone and sodium deoxycholate are added as inhibitors. Blood is

not added to this formulation. Once inoculated with stool, this plate should be incubated in a microaerophilic and capnophilic environment at 42°C.

Campylobacter thioglycolate broth

Campylobacter thioglycolate broth (Campy-Thio) is a selective liquid medium used to enhance the isolation of *Campylobacter* spp. It also is used as a holding or transport medium for these organisms. The base medium is thioglycolate broth with 0.16% agar, and the selective component is the antimicrobial formulation used in Campy-BA.

Cefsulodin-Irgasan-novobiocin

Cefsulodin-irgasan-novobiocin (CIN), also known as *Yersinia*-selective agar, is used to select for the isolation of *Yersinia enterocolitica* in stool samples. Peptones, beef, and yeast extracts are added as nutrient sources. Sodium deoxycholate, cefsulodin, novobiocin, irgasan, and crystal violet are used to inhibit the growth of other organisms found in stool. Mannitol is the differentiating agent, and neutral red is the pH indicator. *Yersinia* grows on this medium and ferments mannitol, forming clear colonies with a red center described as a "bull's eye." *Aeromonas* spp. also will grow and ferment mannitol, but the *Aeromonas* colonies have a pink center and an uneven clear periphery. Most other organisms will not grow on this medium.

Cetrimide agar

Cetrimide agar, also known as pseudosel agar or *Pseudomonas*-selective medium, is used to select for *Pseudomonas aeruginosa* in specimens with mixed microbiota. Also, because it inhibits other *Pseudomonas* spp. (except *P. fluorescens*) and closely related organisms, this test medium can be useful in the differentiation of nonglucose-fermenting, gram-negative rods.

This medium contains cetrimide, also called *cetyl trimethyl ammonium bromide* or *hexadecyltrimethyl ammonium bromide*. Produced from bromine, cetrimide is highly inhibitory and has been used as an antiseptic. If the organism can tolerate cetrimide, it will grow on the medium. Magnesium chloride and potassium sulfate stimulate the production of pyocyanin, the blue pigment, and pyoverdine, the yellow-green pigment, characteristically produced by *P. aeruginosa*. Under ultraviolet light, colonies of *P. aeruginosa* will fluoresce a yellow-green because of pyoverdine production stimulated by the low iron content of the medium.

Chocolate agar

Chocolate (CHOC) agar is an enrichment agar that is especially useful in promoting the growth of *Haemophilus* and other fastidious bacterial species. This medium can be made by adding sheep blood while the basal medium is warm enough to lyse the red blood cells, releasing hemoglobin and nicotinamide adenine dinucleotide (NAD). Alternatively, sheep blood may be replaced by 2% hemoglobin and a

chemical supplement solution, such as BBL IsoVitaleX enrichment (Thermo Fisher Scientific, Waltham, MA). The complete medium must contain cell-free hemoglobin and NAD. Either enrichment results in a chocolate brown-colored medium. Plated medium can be stored at 4°C. Plates should be inoculated, streaked for isolation, and incubated at 35°C in CO₂.

CHROMagars

CHROMagars (DRG International, Springfield, NJ) are selective, differential, chromogenic media that have been developed for the isolation and identification of yeast, *Staphylococcus aureus*, *Escherichia coli* O157:H7, and other organisms. Peptone and glucose are present in the basal nutrient agar, to which are added proprietary chromogenic mixtures, antimicrobial agents, and other additives. As a result, particular bacteria will have a typical and predictable colored colony that can be distinguishable from other colonies. These media can be used as primary isolation plates, such as the CHROMagar Orientation that is suggested for urine cultures in place of a blood agar plate, MacConkey agar, or both.

Citrate agar, Simmons

Simmons citrate agar is useful in differentiating gram-negative enteric bacilli. Similar in principle to acetate agar, citrate replaces acetate in this medium, and differentiation is based on the isolate's ability or inability to use citrate as its sole source of carbon. Organisms capable of using citrate also use the medium's ammonium salt as a nitrogen source. The breakdown of the ammonium salt results in a shift of the pH into the alkaline range. At alkaline pH, the incorporated pH indicator bromothymol blue changes from green to blue.

This medium should be inoculated by streaking the organisms onto the slant with a sterile loop or needle. A light inoculum should be used because dead organisms from a heavy inoculum can be a carbon source, producing a false-positive reaction. Inoculated slants should be incubated at 35°C for up to 4 days and monitored daily for the expected color change. Organisms that can use citrate (positive) will grow on the slant and produce a blue color in the slant. Organisms that cannot use citrate (negative) will not grow on the slant.

Columbia agar with and without 5% sheep blood

Columbia agar is a basal nutrient agar that contains peptones derived from casein and meat as well as beef and yeast extracts. The basal medium is suitable for cultivation of several aerobic and anaerobic bacteria found in clinical materials. Additionally, it provides an efficient base for preparation of a variety of enrichment agars that support the growth of more fastidious aerobes and anaerobes (e.g., 5% sheep blood). The addition of sheep blood allows for the detection of hemolytic reactions, although sometimes the β -hemolytic streptococci may look α -hemolytic because of the high carbohydrate content of this medium. Furthermore, the sheep blood will

provide X factor for organisms that require it, but NADase present in the blood will destroy the V factor, so organisms requiring V factor will not grow on this medium.

Columbia agar with colistin nalidixic acid

Columbia agar with colistin nalidixic acid (CNA), referred to as Columbia CNA agar, is an enrichment-selective medium suitable for the isolation of gram-positive cocci such as staphylococci, streptococci, and pneumococci from specimens that might also be expected to contain gram-negative bacilli, especially *Proteus* spp. Sheep blood is the usual enrichment ingredient, and colistin and nalidixic acid are incorporated to inhibit gram-negative overgrowth. Sheep blood also allows detection of hemolytic reactions especially important in the presumptive identification of streptococci.

Cooked meat (chopped meat glucose) medium

Cooked meat medium is useful in the cultivation of anaerobes, especially pathogenic *Clostridium* spp. This medium contains solid meat particles and is excellent for initiating growth from a very small inoculum as well as sustaining culture viability over long periods. It is useful for the cultivation of mixed cultures because all organisms are supported, whereas overgrowth by the more rapid growers is retarded. Tubed medium should be stored at room temperature, but stored tubes should be placed in flowing steam or a boiling water bath for 10 minutes to drive off dissolved gases and then cooled rapidly before inoculating. Cooled tubed media should be inoculated and incubated in a manner appropriate for the species being isolated or subcultured. The digestion of the meat particles indicates the proteolytic activity of cultured organisms. Saccharolytic clostridial species typically produce acid with gas.

Cycloserine cefoxitin fructose agar

Cycloserine cefoxitin fructose agar (CCFA) is a selective, differential medium useful in the isolation and identification of *Clostridioides difficile* from stool specimens of patients suspected of having antibiotic-associated diarrhea with pseudomembranous colitis. The selective antimicrobial ingredients, cycloserine and cefoxitin, inhibit the growth of intestinal normal biota by interfering with cell wall synthesis in gram-positive and gram-negative bacteria. Indigenous bacteria are inhibited, but *C. difficile* is not. Although cycloserine and cefoxitin are incorporated for their selective properties, fructose and a pH indicator, neutral red, are included to confirm that the isolates can ferment this sugar.

A variation of this medium is made with mannitol rather than fructose and uses bromothymol blue indicator. A second variation adds egg yolk suspension so lecithinase and lipase activities can be detected. *C. difficile* grows as a yellow colony and turns the surrounding medium yellow. Plates should be

held for 7 days. If the colonies are viewed under an ultraviolet light, *C. difficile* will fluoresce a gold-yellow color.

Cystine-glucose blood agar

Cystine glucose blood agar is a highly enriched medium used for the recovery of *Francisella tularensis*. The agar base contains beef heart infusion; peptone and L-cystine that provide nitrogen; vitamins; and amino acids. Glucose is the carbon source, and NaCl maintains the appropriate osmotic balance. Enrichment with 2% hemoglobin from rabbit blood provides additional growth factors.

Cystine tryptic agar with sugar

Cystine tryptic (tryptophan [trypticase]) agar (CTA) is a semi-solid base medium that contains no meat or plant extracts and is free from fermentable carbohydrates. It may be made differential by the addition of a carbohydrate (CTA sugar). CTA sugars are used for the determination of fermentation reactions by fastidious organisms.

Alternatively, carbohydrates are available in the form of differentiation disks that can be aseptically added to the base tubed medium as needed. Sterile, tubed CTA sugars should be inoculated with a heavy inoculum, stabbing to a depth of approximately 2 mm below the medium surface. The caps should be tightly closed and the tubes incubated at 35°C for 24 hours. With phenol red as the pH indicator, fermentation is indicated by a color change in the medium from red to yellow.

Decarboxylase test medium (Moeller)

Decarboxylase test medium with an incorporated amino acid is a differential medium useful in the identification of fermentative and nonfermentative gram-negative bacteria. The differential ingredient is one of three amino acids: lysine, arginine, or ornithine. Decarboxylation of the amino acids yields alkaline end products, which are detected by a change in the color of an incorporated pH-sensitive dye, bromocresol purple. The tubed basal medium (no amino acid) serves as a control for reading the reactions.

Decarboxylase tubes and a control tube should be inoculated from a 24-hour culture using a loop. Inoculated tubes should be overlaid with 4 to 5 mm of sterile mineral oil to avoid oxidative deamination of available protein, which would be falsely interpreted as a positive reaction. Inoculated, overlaid tubes should be incubated at 35°C for up to 4 days. Tubes should be checked daily. Early in the incubation, fermentative organisms will ferment glucose, turning the control and all decarboxylase tubes yellow. For these organisms, as the pH drops, the hydrogen ion concentration becomes optimal for decarboxylase activity in the decarboxylase tubes; the subsequent conversion of the amino acid to amines raises the pH, reversing the yellow to purple, whereas the control tube remains yellow. Nonfermenters do not produce the initial yellow color change, and use of the amino acid is indicated when the amino acid-containing tube becomes a deeper purple than the control.

Deoxyribonuclease test agar

Deoxyribonuclease (DNase) test agar (with or without indicator dye) is a differential medium used to detect the production of a DNase exoenzyme by aerobic bacterial species. The differential ingredient is incorporated DNA. Methods available for the detection of DNA degradation include hydrochloric acid precipitation of undegraded DNA and a color change of an incorporated metachromatic dye, such as toluidine blue or methyl green.

Plated medium should be inoculated using a 1- to 2-cm streak or a spot inoculum approximately 5 mm in diameter. Inoculated plates should be incubated aerobically at 35°C for 18 to 24 hours. Following incubation, DNase activity is detected in one of the following ways:

1. If a basal medium without a metachromatic dye was inoculated, flood the plate with 1 N HCl and look for a zone of clearing around the bacterial growth. If the incorporated DNA is undegraded, it is precipitated by the 1 N HCl, and the medium becomes opaque. If the incorporated DNA is degraded, the nucleotide fragments dissolve in the 1 N HCl, and the medium remains clear. A clear halo around the colony is a positive result.
2. If the medium includes toluidine blue, the blue, DNA-bound dye is released from nucleotide fragments, producing a color change to rose. The medium remains clear blue in negative reactions.
3. If the medium includes methyl green, the green, DNA-bound dye is released from nucleotide fragments, resulting in a loss of color. The medium remains green in negative reactions.

Egg yolk agar

Egg yolk agar (EYA), also known as modified *McClung Toabe agar*, is a differential medium useful in the detection of lecithinase, lipase, and protease activity. Incorporated egg emulsion provides the lecithin, lipids, and proteins to be degraded by these enzymes. Exoenzyme activity is detected on EYA. Lecithinase activity produces a zone of opacity immediately around the growth streak, lipase activity results in an iridescent sheen on or around the surface of colonies, and protease activity is seen as a clearing of the medium around and just beyond the streaked growth area. An organism can produce one or all of these exoenzymes.

Plated medium is inoculated as a single streak across the plate and incubated anaerobically at 35°C for 24 to 72 hours. If the Nagler test is to be performed, one half of the plate surface should be smeared with a few drops of *Clostridium perfringens* type A antitoxin before inoculation. The inoculation streak should then extend across both halves (no antitoxin-antitoxin) of the plate. Plates should be incubated anaerobically at 35°C for 24 to 48 hours. A positive test result is the inhibition of lecithinase activity on the half of the plate with antitoxin. Plated medium not used immediately can be stored at 4°C if it is sealed in plastic bags.

Eosin-methylene blue agar

Eosin-methylene blue (EMB) agar is a selective differential medium useful in the isolation and identification of

gram-negative enteric bacteria. The dyes eosin Y and methylene blue make the medium selective by inhibiting the growth of gram-positive bacteria while allowing the growth of gram-negative ones. The carbohydrates lactose and sucrose are incorporated to allow differentiation of isolates based on lactose or sucrose fermentation. Fermentation is detected by color changes and precipitation of the incorporated dyes as the pH drops. Sucrose serves as an alternative carbohydrate source for slow lactose fermenters, allowing their timely elimination from consideration as possible pathogens. *E. coli*, a rapid lactose fermenter, typically forms blue-black colonies with a metallic greenish sheen. Other Enterobacterales fermenters, such as *Enterobacter*, form pink colonies. Nonfermenter colonies are translucent and colorless or light purple.

Esculin agar

Esculin agar is a differential medium used to determine the ability of an organism to hydrolyze esculin. The hydrolytic product from esculin, esculetin, reacts with the ferric salt present in this medium to precipitate iron compounds and produce a gray to black discoloration of the medium. The medium should be inoculated, incubated aerobically at 35°C, and observed for growth, with darkening of the medium indicative of esculin hydrolysis.

Fletcher semi-solid medium for *Leptospira*

Fletcher semi-solid medium is an enrichment medium recommended for the recovery of leptospiral species in blood, cerebrospinal fluid, urine specimens, and possibly contaminated water and other materials. The enrichment component of this medium is rabbit serum containing hemoglobin.

The lyophilized rabbit serum with hemoglobin is commercially available as *Leptospira* Enrichment, or sterile, pooled, fresh natural rabbit serum may be used. The medium should be aseptically dispensed into sterile, screw-capped tubes (5mL/tube) and stored at room temperature overnight. The complement in the medium must be inactivated by placing tubes in a 56°C water bath for 1 hour on the day following preparation. Cooled inactivated medium should be inoculated with one or two drops of the fluid specimen. Small inocula introduced into multiple tubes are recommended to optimize pathogen recovery and minimize any interference by antibodies in the body fluid specimens. Inoculated tubes should be incubated with caps loosened at 25° to 30°C for 4 to 5 weeks and examined weekly for growth in the form of turbidity at the top of the medium. A loopful of fluid from any tube showing turbidity should be placed on a slide, a coverslip added, and the specimen examined by dark-field microscopy. Medium can be made selective by incorporating 5-fluorouracil. Ellinghausen-McCullough-Johnson-Harris medium can also be used for recovery of leptospires in clinical specimens.

GC-Lect agar

GC-Lect agar (BD Diagnostic Systems) is a selective medium that provides enhanced growth and recovery of *N. gonorrhoeae*

and inhibits contaminating organisms. GC-Lect agar includes inhibitors that prevent overgrowth of pathogenic *Neisseria* spp. in specimens containing contaminating strains resistant to the inhibitors in modified Thayer-Martin (MTM) agar; for example, vancomycin-resistant *Staphylococcus epidermidis*. The medium contains lincomycin, vancomycin, trimethoprim, colistin, and amphotericin B. To improve recovery of *N. gonorrhoeae* strains that are sensitive to vancomycin, the concentration of this antibiotic in GC-Lect agar is decreased compared to MTM.

Gram-negative broth

Gram-negative (GN) broth is a selective enrichment medium used to enhance the recovery of enteric pathogens *Salmonella* and *Shigella* spp., from fecal specimens. The selective ingredients are deoxycholate and citrate salts, which inhibit the growth of gram-positive bacteria and some gram-negative bacilli, while allowing the growth of *Salmonella* and *Shigella* spp. Enrichment is provided by increasing the concentration of mannitol, which temporarily favors the growth of mannitol-fermenting, gram-negative bacilli (*Salmonella* and *Shigella*) over that of the mannitol nonfermenters (e.g., *Proteus*).

Sterile tubed media should be inoculated with fecal material and incubated, with caps loosened, at 35°C. Incubated GN broth cultures should be subcultured onto selective, differential plated media after 6 to 8 hours and again after 18 to 24 hours.

Haemophilus test medium

Susceptibility testing of *Haemophilus* isolates is performed on the enriched *Haemophilus* test medium. This medium has a clear agar base and includes beef, yeast, and casein extracts as well as hematin and NAD. This formulation can also be made as a liquid and used for broth minimal inhibitory concentration (MIC) determinations of *Haemophilus* spp.

Hektoen enteric agar

Hektoen enteric (HE) agar is a selective differential medium used for direct isolation of enteric pathogens from feces and for indirect isolation from selective enrichment broth, e.g., GN broth. The selective ingredients are bile salts at concentrations that not only inhibit the growth of gram-positive bacteria, but also inhibit the growth of many gram-negative organisms that are part of the normal intestinal microbiota. The differential ingredients include lactose, salicin, and sucrose to determine fermentation patterns, detected by the pH indicator bromothymol blue; and ferric salts (sodium thiosulfate, ferric ammonium citrate) to detect the production of H₂S gas.

This medium should not be autoclaved, and overheating should be avoided. Plated medium should be inoculated, streaked for isolation, and incubated aerobically (not in CO₂) at 35°C for 18 to 24 hours. Most nonpathogens ferment one or both of the sugars, and colonies appear bright orange to salmon pink because of the low pH interaction with incorporated dyes. Nonfermenters, such as *Salmonella* and *Shigella*

spp., typically produce green to blue-green colonies. H₂S gas production is detected as a black precipitate that accumulates within the center of colonies.

Kligler iron agar

Kligler iron agar (KIA) can be used to determine whether a gram-negative rod is a glucose or lactose fermenter or both. The medium also tests for gas production during carbohydrate fermentation and H₂S production, both of which are useful in the differentiation of gram-negative rods belonging to the Enterobacterales.

KIA contains glucose and lactose (fermentable carbohydrates), where lactose is present at 10 times the glucose concentration; phenol red (pH indicator); peptone (carbon-nitrogen source); and sodium thiosulfate plus ferric ammonium sulfate (sulfur source and H₂S indicator, respectively). KIA resembles triple sugar iron (TSI) agar, except that it lacks sucrose. By convention, when reading the reactions, shorthand is used—the reaction of the slant is put over the reaction in the butt, and K is used for alkaline and A for acid. The following three carbohydrate fermentation patterns are possible:

1. Alkaline (red) slant and acid (yellow) butt (K/A) indicate that the organism ferments glucose but not lactose. This organism ferments glucose by the Embden-Meyerhof pathway to produce organic acids, changing the pH indicator from red to yellow. Once the glucose has been consumed, the organism then breaks down peptones, producing ammonia. The breakdown of peptones happens only aerobically and results in an increase in pH; thus the slant reverts to red.
2. Acid (yellow) slant and acid (yellow) butt (A/A) indicate that the organism ferments both glucose and lactose. The organism ferments glucose, producing acid products. Once the glucose is consumed, it ferments lactose, breaking it down into glucose and galactose, causing the pH in the slant portion to remain acidic.
3. Alkaline (red) slant and alkaline (red) butt (K/K) indicate that the organism cannot ferment glucose or lactose and therefore produces no acidic products. The slant may become redder because of peptone catabolism. Often, with the lack of glucose fermentation, the butt is the same color as the butt of an uninoculated tube. Therefore some sources prefer the designation “no change” (NC) as opposed to alkaline.

If there are gas bubbles in the butt, splitting of the medium, or displacement of the medium from the bottom of the tube, the organism is aerogenic; that is, it can produce CO₂ and hydrogen gases during fermentation. This designation is noted in the shorthand designation as “g” (e.g., A/Ag). Any blackening in the butt indicates that the organism produces H₂S gas from thiosulfate. The H₂S combines with iron salt to produce ferrous sulfide, a black precipitate. H₂S is added after the slant/butt shorthand to signify that the organism produces H₂S (e.g., K/A H₂S).

With an inoculating needle that has a sample of a pure culture of the isolate, inoculate the medium by stabbing the butt and streaking the slant. The cap should be slightly loose. If the cap is screwed on too tightly, there will not be sufficient oxygen for peptone catabolism and, as a result, gram-negative

rods able to ferment only glucose may appear as lactose fermenters. Reactions should be interpreted at 18 to 24 hours. If the medium is read earlier, organisms able to ferment only glucose may appear to be lactose fermenters. If the medium is read later, lactose fermenters may consume the lactose and begin to catabolize peptones, with the slant reverting to red. A yellow slant and red butt may indicate failure to stab the butt or inoculation of the medium with gram-positive organisms. Examining the medium for a stab line or performing a Gram stain should clarify this situation.

The H₂S indicator system in KIA is not as sensitive as that found in other media, such as sulfide indole motility agar. A black butt should be read as acid, even though the yellow color may be obscured. If H₂S is reduced, this indicates that an acid condition does exist and can be assumed. Critical to understanding how this medium works is the fact that glucose is present in 10% the amount of lactose. Organisms use the simplest carbohydrate, glucose, first; once this is consumed, the organisms attack the more complex carbohydrate, lactose. If the organisms lack the appropriate enzymes, they move on to protein catabolism. There is sufficient lactose in the medium to prevent breakdown of peptone, provided it is read at the appropriate time.

Lim broth

Lim broth is used for the isolation of *Streptococcus agalactiae*, usually from vaginal or rectal swabs obtained from pregnant women who are being screened for group B streptococci carriage before delivery. Lim broth is a modified Todd-Hewitt broth. The Lim broth contains peptones, yeast extract, and glucose to support the growth of streptococci. Colistin and nalidixic acid are added to inhibit the growth of gram-negative organisms.

Lim broth is inoculated with the vaginal or rectal swab and incubated at 35°C with cap loosened for 18 to 24 hours. At this time, the broth is subcultured to a blood agar plate and then incubated at 35°C in 5% CO₂ for 24 hours. The plate is then examined for the presence of β-hemolytic colonies. If no such colonies are present after the first incubation, the plate should be reincubated and reexamined after another 24-hour incubation period.

Loeffler medium

Loeffler agar slant is used primarily for the recovery and identification of *Corynebacterium diphtheriae*. This medium contains beef serum, heart muscle infusion, and peptic digest of animal tissue. It can be used for the primary recovery of *C. diphtheriae* from nose and throat specimens and for subculture purposes. Because Loeffler medium is so enriched, *C. diphtheriae* grows well within 12 to 16 hours and produces non-distinctive translucent to gray-white colonies. The medium promotes the development of characteristic metachromatic granules that can be observed microscopically with methylene blue stains. High serum content and the incorporation of eggs enables the detection of proteolytic activity. Positive organisms produce colonies surrounded by small holes containing liquefied medium. The entire slant may eventually turn to liquid and produce a foul odor.

Loeffler serum slant should be inoculated as soon as possible after specimen collection, and selective media containing tellurite should always be used as well. Smears for *C. diphtheriae* should be prepared and examined after 8 to 24 hours of incubation. Although granule formation is typical of *Corynebacterium* spp., other organisms can produce a similar microscopic appearance. Therefore additional testing must be performed for confirmation of this organism.

Löwenstein-Jensen medium

Löwenstein-Jensen (LJ) medium is used to cultivate *Mycobacterium* spp. The potato flour, egg, and glycerol included in LJ medium help detoxify this medium and also supply nutrients required for growth of these organisms. Asparagine is included for maximum production of niacin by certain *Mycobacterium* spp. The malachite green inhibits the growth of other bacteria that may be present in specimens.

LJ medium is good for 1 month if tightly capped to prevent moisture loss and stored at 4° to 6°C. LJ medium must be kept out of direct light because malachite green is light-sensitive. Decontaminated, digested, or untreated specimens are inoculated onto the medium and incubated in a CO₂ incubator (5% to 10% CO₂) for 6 to 10 weeks. It is important to leave caps loosened for proper gas exchange. LJ medium can be prepared as deep tubes to be used in semi-quantitative catalase testing to help identify the *Mycobacterium* spp. LJ medium with 5% NaCl may be prepared to aid in identifying rapid growers. This medium is the same as LJ except that 5 g of NaCl is added per 100 mL of medium. The additional salt allows for testing the ability of certain mycobacteria to tolerate and grow in the presence of a high salt concentration.

Löwenstein-Jensen medium (Gruft modification)

LJ medium (Gruft modification), also known as *Löwenstein-Gruft medium*, is an enriched selective medium for the isolation of mycobacteria. The Gruft modification makes this medium more selective through the addition of penicillin (50 U/mL) and nalidixic acid (35 µg/mL). This formulation also includes 0.05 µg/mL of ribonucleic acid, which increases the rate of mycobacterium isolation over the standard LJ formulation. In the Petran and Vera modification, cycloheximide, lincomycin, and nalidixic acid are added to make LJ more selective. Both modifications can permit gentler decontamination or digestion procedures.

Lysine iron agar

Lysine iron agar (LIA) measures three parameters useful in identifying species of Enterobacteriales: lysine decarboxylation, lysine deamination, and H₂S production. LIA contains lysine (amino acid), glucose (carbohydrate source), a small amount of protein, bromocresol purple (pH indicator), and sodium thiosulfate and ferric ammonium citrate (sulfur

source and H₂S indicator). A purple color denotes an alkaline environment, designated P. Also, an R is used for the Bordeaux red color.

Three lysine-use patterns are possible:

1. Alkaline (purple) slant and alkaline (purple) butt (P/P) indicate that the organism decarboxylates lysine but cannot deaminate it. Initially, the organism ferments glucose, causing production of acid and changing the indicator in the butt to yellow. The organism then decarboxylates lysine to produce cadaverine, an alkaline product, which causes the pH indicator to change from yellow back to purple.
2. Alkaline (purple) slant and acid (yellow) butt (P/A) indicate that the organism fermented the glucose but was unable to deaminate or decarboxylate the lysine.
3. A red slant and acid (yellow) butt (R/A) indicate that the organism deaminated lysine but could not decarboxylate it. The yellow butt is caused by glucose fermentation. The red slant results from the product of lysine deamination combining with ferric ammonium citrate and flavin mononucleotide to form a burgundy color on the slant.

Any blackening in the butt indicates production of H₂S from sodium thiosulfate. This gas reacts with ferric salt to produce the black precipitate, ferrous sulfide. This medium appears purple before use. LIA is inoculated by stabbing the butt twice and streaking the slant with an inoculating needle. The cap should be left slightly loose because oxygen is required for deamination detection. Reactions should be read after 18 to 24 hours of incubation at 35°C. The medium may be incubated for up to 48 hours if needed. LIA is not as sensitive as other media for H₂S detection. Typically, H₂S-producing *Proteus* spp. may appear negative. Also, *Morganella morganii* produces a variable lysine deamination reaction after 24 hours of incubation. This medium can only be used with organisms that can ferment glucose. LIA is not a replacement for the Moeller decarboxylase tests.

MacConkey agar

MacConkey agar (MAC) is a selective, differential, primary plating medium. It selects for Enterobacteriales and other gram-negative bacilli in the presence of mixed microbiota and differentiates them into lactose fermenters and nonlactose fermenters. Bile salts and crystal violet inhibit most gram-positive organisms but permit growth of most gram-negative rods.

Lactose serves as the sole carbohydrate source. Gram-negative rods that ferment lactose produce pink or red colonies, which may be surrounded by precipitated bile. Acid production from lactose fermentation causes the neutral red dye absorbed into the colonies to change to red and can also cause the bile salts to become insoluble. Nonlactose-fermenting, gram-negative bacilli produce colorless or transparent colonies. Plates are streaked for isolation and incubated in ambient air, not in a CO₂ incubator, for 18 to 24 hours at 35°C. Weak, slow, or late lactose fermenters can produce colorless colonies at 24 hours or appear slightly pink in 24 to 48 hours. Plates should not be incubated longer than 48 hours because this can lead to confusing results.

Some gram-negative bacilli may fail to grow on this medium, whereas with prolonged incubation, some gram-positive bacteria, such as *Enterococcus* spp., can produce tiny colonies. Room temperature incubation may enhance recovery of *Yersinia enterocolitica*. The agar concentration may be increased to prevent swarming of *Proteus* spp. A formulation of MAC without crystal violet has been used to help identify mycobacteria.

MacConkey sorbitol agar

MacConkey sorbitol agar contains the same components as MAC, except D-sorbitol is substituted for lactose. This medium has been used to screen for *E. coli* O157:H7, which does not rapidly ferment sorbitol. Plates should be incubated at 35°C for 24 hours. Sorbitol-negative colonies will appear colorless on this medium and indicate possible *E. coli* O157:H7. Most other clinical isolates of *E. coli* produce a pink to red color on this medium.

Malonate broth

Malonate broth is used in the identification of species of Enterobacterales, particularly *Salmonella*. The broth contains sodium malonate (the primary carbon source), small quantities of glucose and yeast extract (nutrients), bromothymol blue (pH indicator), various salts, and a buffering system. Organisms producing a Prussian blue color can use malonate as a carbon source. If they can use malonate as a carbon source, they will also use ammonium sulfate as a nitrogen source, thereby producing alkaline products that cause an increase in pH and a change in the color of the medium to blue. Organisms unable to use malonate as a carbon source usually fail to grow, and the medium stays green. Because malonate resembles succinate, it competitively binds to succinate dehydrogenase, which catalyzes the succinate to fumarate reaction in the Krebs cycle. The inhibition of this enzyme, coupled with the inability to use malonate as a carbon source, prevents growth of the malonate-negative organism.

Malonate broth should be inoculated from triple sugar iron agar, KIA, or broth culture. The inoculum should be light. Cultures should be incubated at 35°C, checked at 18 to 24 hours, and checked again at 48 hours for production of a blue color. Some organisms produce only small amounts of alkalinity. Any trace of blue should be considered positive. Comparison with an uninoculated tube may be useful. Production of a yellow color is a negative reaction and is probably caused by fermentation of the small amount of glucose in the medium.

Mannitol salt agar

Mannitol salt agar is a selective and differential primary culture medium useful in the recovery and identification of staphylococci from specimens containing mixed microbiota. A high salt concentration (7.5%) inhibits most gram-negative and gram-positive bacteria except *Staphylococcus* spp. *S. aureus* can ferment mannitol, the sole carbohydrate in the

medium, to produce acid products. This lowers the pH and changes the color of the pH indicator, phenol red, to yellow. Plates are streaked for isolation and incubated at 35°C for 24 to 48 hours in ambient air. Colonies of *S. aureus* typically appear yellow, surrounded by a yellow zone. Most other *Staphylococcus* spp. usually do not ferment mannitol and therefore produce reddish colonies that may exhibit a red surrounding zone because of peptone breakdown. However, *Staphylococcus capitis*, *Staphylococcus xylosus*, and other staphylococci are mannitol positive and produce yellow colonies.

Enterococcus may be able to grow on mannitol salt agar and weakly ferment mannitol. Differentiation is readily accomplished through a catalase test. With prolonged incubation, organisms other than staphylococci can begin to grow and ferment mannitol. Some strains of *S. aureus* may slowly ferment mannitol, so plates should not be discarded until after 48 hours of incubation. All colonies suggestive of *S. aureus* should be further tested for coagulase or with another acceptable procedure. Subculture to less selective agar is preferable before performing these tests.

Methyl Red Voges-Proskauer medium

Methyl red Voges-Proskauer (MRVP) medium broth is useful in distinguishing among members of the Enterobacterales. For example, *E. coli* is positive for methyl red and negative for Voges-Proskauer; *Enterobacter aerogenes*, *Enterobacter cloacae*, and *Klebsiella pneumoniae* show the reverse reactions. Members of the Enterobacterales can be divided into two groups based on how they metabolize glucose. One group produces large amounts of mixed acids (lactic, formic, succinic, and acetic). When methyl red is added to one of these cultures after incubation, a red color is produced because of the acidic pH. The other group produces predominantly neutral end products, acetoin or acetylmethylcarbinol, by the butylene glycol pathway. When α -naphthol and 40% potassium hydroxide are added to the broth culture containing a member of this latter group, acetoin (if present) is oxidized to diacetyl in the presence of air and base. α -Naphthol catalyzes a reaction between the diacetyl and guanidine components of peptone to produce a pink-red color.

For the methyl red test, the broth culture is inoculated with a light inoculum and must be incubated for 48 hours. After incubation, the broth is divided into two tubes. The Voges-Proskauer test was originally designed to be performed after 5 days of incubation at 30°C. By using 0.5 to 1 mL of broth per tube, the test can be done after 18 to 24 hours of incubation at 35°C. Shaking aerates the broth culture and enhances the reaction. Enterobacterales are typically positive for methyl red or Voges-Proskauer, but not both.

Middlebrook 7H10 and 7H11 agars

Middlebrook 7H10 and 7H11 agars are used to cultivate *Mycobacterium* spp. Isoniazid-resistant strains grow better on these media, especially Middlebrook 7H11, than on egg-based media such as LJ medium. The Middlebrook agars are also more chemically defined than the LJ formulations. Middlebrook 7H10 and 7H11 are similar, except 7H11 contains

casein hydrolysate, which stimulates the growth of drug-resistant *Mycobacterium tuberculosis*. Both media contain growth factors, such as amino acids, glycerol, and inorganic salts that encourage recovery of mycobacteria. In addition, both formulations include OADC (oleic acid–dextrose catalase) enrichment, which chemically simulates egg components. The oleic acid is a fatty acid used by the mycobacteria. Albumin is added to inhibit toxic agents that might be present and to provide a source of protein. The added dextrose (glucose) is used by the mycobacteria to generate energy. The exogenous catalase neutralizes toxic peroxides. Malachite green is also added, although at a lower concentration than in LJ, and it gives some selectivity to the medium. Incubation in an aerobic atmosphere enriched with CO₂ is recommended.

Mitchison 7H11 selective agar

Mitchison 7H11 selective agar is prepared by adding antimicrobial agents to the Middlebrook 7H11 formulation, thereby making the medium more selective for mycobacteria. Amphotericin B, carbenicillin, polymyxin B, and trimethoprim are typically incorporated to inhibit gram-negative bacilli in particular, as well as yeast.

Motility test medium

The purpose of motility test medium is to determine whether an organism is motile or nonmotile. This test is particularly useful to identify members of the Enterobacterales in which two genera, *Shigella* and *Klebsiella*, are always nonmotile, and certain *Yersinia* spp. show motility at room temperature but not at 35°C. The nonglucose-fermenting, gram-negative bacilli can also be differentiated based in part on their motility. Furthermore, *L. monocytogenes* gives a classic, umbrella-shaped motility pattern below 30°C.

Nonmotile organisms, which lack flagella, grow only along the stab line, and the surrounding medium remains clear. Motile organisms, which usually possess flagella, move out from the stab line, and the medium appears turbid. A low agar concentration makes the medium semi-solid and permits better detection of motility. The medium is inoculated using an inoculating needle to stab the middle of the medium straight down and up once, without going all the way to the bottom of the medium. It is important to be careful and remove the inoculating needle along the initial stab line. Motility media should be incubated at 35°C. Because flagellar protein is not formed as well at higher temperatures, incubation at 20°C to 22°C is recommended. For *Yersinia* and *Listeria* species, noting the motility reaction at room temperature is particularly useful.

Triphenyltetrazolium chloride (TTC) may be added to the basic motility medium to enhance detection of motility. A 1% solution of TTC is prepared and filter-sterilized, and 5 mL of this solution is added to 1 L of motility medium. If TTC is used, bacteria incorporate colorless TTC and reduce it to a red formazan pigment. The medium shows reddening where there is growth. Other media such as sulfide indole motility (SIM) and motility indole ornithine (MIO) can be used to detect motility in addition to other reactions.

Mueller-Hinton agar

Mueller-Hinton agar is a transparent medium used in susceptibility testing of organisms to antimicrobial agents. Because Mueller-Hinton agar contains animal infusion, casein extract, and starch, it supports the growth of most organisms. In addition, sheep blood may be added to the basic formulation to perform susceptibility testing on streptococci, in particular *Streptococcus pneumoniae*. The addition of heated or chocolate sheep red blood cells to Mueller-Hinton agar makes an enriched medium that can be used for susceptibility testing of fastidious organisms, such as *Haemophilus* and *Neisseria*. Muller-Hinton agar also can be used for the X and V Factor test for *Haemophilus* spp. Starch is included in the medium for two reasons: it may protect the organisms against toxic substances and it can also serve as an energy source for some bacteria. Ca²⁺ and Mg²⁺ concentrations are critical in the testing of *Pseudomonas* isolates with aminoglycoside antibiotics. Usually, Mueller-Hinton agar contains enough bivalent cations, but it may be necessary to add these substances to Mueller-Hinton broth.

Mueller-Hinton agar with 2% NaCl

The addition of 2% NaCl to the basic Mueller-Hinton medium results in a medium that is selective for staphylococci. This formulation is used to detect methicillin-resistant *Staphylococcus aureus* (MRSA). The slower-growing resistant cells can be missed in a mixed population with methicillin-sensitive strains. Cefoxitin or oxacillin using the Kirby-Bauer method or Etest is useful in detecting MRSA. Once inoculated, the medium should be incubated at 30° to 35°C up to 48 hours to detect the heteroresistant methicillin-resistant isolates more accurately.

Mueller-Hinton agar with 4% NaCl and 6 µg/mL oxacillin

For this variation, 4% NaCl and 6 µg/mL oxacillin are added to the basic Mueller-Hinton medium to screen *S. aureus* isolates selectively for resistance to oxacillin or nafcillin. The inoculated plate should be incubated for 24 hours at 35°C in ambient air and examined using transmitted light for the presence of colonies.

Mycobactosel L-J medium

Mycobactosel, a BBL trade name, is a selective medium for the isolation of mycobacteria from specimens containing mixed biota. The medium contains cycloheximide, lincomycin, and nalidixic acid to inhibit contaminating organisms. Cycloheximide controls the growth of saprophytic fungi, while lincomycin inhibits gram-positive bacteria. Growth of some contaminating gram-negative bacteria encountered in clinical specimens is inhibited by nalidixic acid. The medium contains egg, glycerol, asparagine, malachite green, and other

various inorganic salts and nitrogen sources to support the growth of mycobacteria. Glycerol is a source for carbon and energy; asparagine promotes growth, and egg yolk is a source of lipids. Malachite green partially inhibits growth of contaminating bacteria.

New York City medium

New York City (NYC) medium is primarily used to isolate *N. gonorrhoeae* and *N. meningitidis* from specimens containing mixed normal microbiota. This medium will also support the growth of some mycoplasmas as well as *Ureaplasma urealyticum*. NYC medium is enriched with hemoglobin from lysed horse erythrocytes, yeast dialysate, and horse plasma. Selectivity for *N. gonorrhoeae* and *N. meningitidis* is accomplished by incorporating four antimicrobial agents that inhibit normal biota. Vancomycin prevents the growth of gram-positive bacteria, colistin inhibits gram-negative bacilli, and amphotericin B prevents the growth of yeast and molds. Trimethoprim is included to prevent swarming of *Proteus* spp. The concentrations of these antimicrobial agents are lower compared with MTM agar. Inoculated NYC plates should be incubated in increased CO₂ for several days. Also, a nonselective agar, such as CHOC agar, should be inoculated because 5% of gonococci are inhibited by the antimicrobial agents, particularly vancomycin and trimethoprim, found in this medium.

Nitrate broth

Nitrate broth is used to determine whether an organism can reduce nitrate to nitrite or to gaseous end products, such as nitrogen. The test is useful in identifying members of Enterobacterales and differentiation of nonglucose-fermenting, gram-negative rods, *Neisseria* spp., and *Moraxella catarrhalis*. The nitrate broth is inoculated with the test organism and incubated for 18 to 24 hours at 35°C.

The determination of nitrate reduction is performed in two parts. Sulfanilic acid and *N,N*-dimethyl-1-naphthylamine reagents are added first. If nitrate has been reduced to nitrite, nitrite will react with these reagents to form a red diazonium dye, *p*-sulfobenzene-azo- α -naphthylamine, and the test is positive. If there is no color change, then nitrate was not reduced or the nitrate was reduced to nitrogen gas. In this situation, zinc dust is added. Zinc reduces the remaining nitrate to nitrite, forming a red color. If nitrates are still present and a red color appears after the addition of zinc, then the organism is nitrate reduction-negative. However, if nitrate was reduced to nitrogen gas, no color change occurs, and the test is interpreted as positive. The presence of gas can be detected by putting a Durham tube into the broth before incubation. Gas produced during nitrate reduction will be captured in the inverted tube and seen as a bubble.

The results should be determined immediately after the addition of the reagents because the color fades quickly. If it is necessary to add zinc, avoid using large amounts. Too much zinc can result in the formation of hydrogen gas, which can cause reduction and decrease the color reaction. The medium may need to be supplemented with serum and incubated for

up to 5 days when testing *Neisseria* spp. An uninoculated control tube using the reagents should be performed alongside the patient test tube to ensure that glassware, reagents, and supplies are nitrate free.

Nutrient agar

Nutrient agar has been used to distinguish between the non-fastidious, less pathogenic *Neisseria* spp. and pathogenic *Neisseria* spp., such as *N. gonorrhoeae* and *N. meningitidis*. Nutrient agar contains minimal nutrients and an especially low concentration of protein. Growth of an isolate on this medium means that it is not fastidious and does not require special supplements. The less fastidious neisseriae grow on nutrient agar, whereas the more pathogenic species do not. Nutrient agar has also been used for the maintenance of stock cultures.

Oxidative-fermentative medium (Hugh and Leifson formulation)

Oxidative-fermentative (OF) medium is used to determine whether a gram-negative, nonglucose-fermenting rod is oxidative, fermentative, or biochemically inert. Three modifications over traditional media make this medium useful in testing nonfermenting gram-negative bacilli. A low concentration of peptone prevents the formation of alkaline products that can neutralize small quantities of acid produced through oxidation. The high concentration of carbohydrate increases the potential amount of acid that can be formed, and the lower concentration of agar makes the medium semi-solid, permitting acids formed on the surface to diffuse throughout the medium. Bromothymol blue serves as the pH indicator for acid detection.

The classic method for using this medium involves the stabbing of two tubes with the organism. The medium in one tube is covered with vaspar (a mixture of petrolatum and paraffin) or melted paraffin. Sterile mineral oil has been used for this purpose but is not recommended because it does not block oxygen as well. Tubes are incubated at 35°C. Several days of incubation may be required because of the slower growth of some nonfermenting gram-negative bacilli. A color change to yellow in both tubes means that the organism is fermentative (i.e., it can produce acid in the absence of oxygen). Color change to yellow in only the uncovered tube means that the organism is oxidative (requires oxygen to use the carbohydrate). If neither tube changes in color or the covered tube shows no change but the uncovered tube turns blue, the organism cannot use the carbohydrate oxidatively or fermentatively and is considered inert.

A one-tube modification of this test has been described. One tube is stabbed, and it is not covered. Color change to yellow only near the top of the medium indicates the oxidative use of glucose. If the entire tube changes to yellow, fermentation is suggested. Because the medium is semi-solid, motility may be observed in this medium. Sometimes OF medium is used for differentiating staphylococci (fermentative) from micrococci (oxidative). This testing requires a different formulation.

Oxidative-fermentative base, polymyxin B, bacitracin, lactose agar

Oxidative-fermentative base, polymyxin B, bacitracin, lactose agar (OFPBL) is a selective and differential medium used for the isolation of *Burkholderia cepacia* from respiratory samples of patients with cystic fibrosis. Polymyxin B and bacitracin are added to inhibit the growth of most gram-negative and gram-positive bacteria. The medium differentiates between colonies that grow based on the ability of the isolate to ferment lactose. *B. cepacia* can ferment lactose and appears as a yellow colony. Nonlactose-fermenting colonies that grow appear green. OFPBL plates should be inoculated with the specimen and incubated aerobically at 30°C.

Phenylalanine deaminase agar

Phenylalanine deaminase (PAD) agar is used to detect an organism's ability to deaminate phenylalanine. A positive reaction is most useful for distinguishing *Proteus*, *Providencia*, and *Morganella* spp. from other members of Enterobacterales. This test also can be used to distinguish phenylpyruvate-positive *Moraxella* organisms from other *Moraxella* spp.

PAD agar includes phenylalanine, yeast extract, a nitrogen and carbon source, various salts, and agar. Protein hydrolysates and meat extracts are not included because these substances contain a variable amount of phenylalanine. The PAD slant is inoculated with the test organism, and the slant is incubated at 35°C for 18 to 24 hours. At the end of the incubation period, a few drops of 12% FeCl₃ are added to the tube so they will run down the slant. If an organism produces phenylalanine deaminase, it converts phenylalanine to the α -keto acid, phenylpyruvic acid. This acid reacts with the ferric chloride reagent to form a dark green complex. The immediate appearance of a dark green slant on addition of ferric chloride reagent is a positive reaction; no color change on addition of reagent is a negative reaction.

Phenylethyl alcohol agar

Phenylethyl alcohol (PEA) agar is used primarily to isolate gram-positive cocci, such as staphylococci and streptococci, from specimens with mixed microbiota. Most gram-positive bacilli will also grow on this medium, except *Bacillus anthracis*, which is unique among the *Bacillus* spp. in its lack of growth on this medium.

PEA agar resembles sheep blood agar except that PEA contains phenylethyl alcohol. This component inhibits facultative gram-negative rods, especially swarming *Proteus* spp. PEA is volatile, and plates should be tightly sealed in plastic bags and stored in the refrigerator. Hemolytic reactions are not dependable on this medium because of the action of PEA on cell membranes. Gram-negative rods can grow on PEA agar, but colonies are smaller than usual and can be readily differentiated from those of gram-positive bacteria. *P. aeruginosa* is not inhibited by this medium. Some gram-positive cocci may require more than 24 hours of incubation to grow

well on PEA agar. An anaerobic formulation can be achieved by adding PEA to CDC anaerobic agar before autoclaving or by supplementing the formulation with hemin, vitamin K, and sheep blood after sterilization of basal medium. The anaerobic formulation of this medium selects for gram-negative and gram-positive obligate anaerobes while inhibiting facultatively anaerobic gram-negative bacilli.

Tellurite blood agar

Tellurite blood agar is a selective, differential, enrichment agar useful in isolating *Corynebacterium diphtheriae*. Animal blood or hemoglobin powder and vitamin growth supplement are added as enrichment. Some formulations also incorporate cystine to enhance the growth of fastidious organisms further, including *C. diphtheriae*. Potassium tellurite is the selective and differential ingredient responsible for inhibiting the growth of gram-negative organisms, staphylococci, and streptococci while allowing the growth of *C. diphtheriae* and diphtheroids. *C. diphtheriae* reduces the tellurite, resulting in a black colony.

Tubes of base medium can be stored and melted to make the complete medium as culture plates are needed. Freshly plated medium should be inoculated, streaked for isolation, and incubated at 35°C. On this medium, colonies of *C. diphtheriae* are dull gray-black, whereas diphtheroids are light gray-green with dark centers. Some *Staphylococcus* spp., gram-negative bacilli, and yeasts may overcome inhibition and grow on this medium. The *Staphylococcus* colonies are large, glistening, and jet black, whereas those of gram-negative bacilli and yeasts are dull gray-black but larger than the *C. diphtheriae* colonies.

PPLO agar

PPLO agar is used to isolate *Mycoplasma* spp. Its name is derived from the original name for *Mycoplasma*: a *pleuropneumonia-like organism*. Nutrients in this medium are provided by yeast-enriched peptones, serum, and heart infusion. NaCl is added to maintain proper osmotic pressure. Agar is added to solidify the medium, but at a lower concentration than in other solid agar plates. With less agar, the medium is softer so the mycoplasmas can grow into the medium and grow only slightly on top of the plate. Antimicrobials can be added to inhibit the growth of other bacteria. The medium should be inoculated with the specimen and incubated at 35°C in 5% to 10% CO₂. Plates should be examined under a stereomicroscope for the growth of small (0.01- to 0.5-mm diameter) colonies, some of which might have a dense center surrounded by a less dense periphery (fried egg-like). Plates should be saved for at least 7 days before they are discarded as negative.

Regan-Lowe medium

Regan-Lowe medium is enriched and selective for the isolation of *Bordetella pertussis* and *Bordetella parapertussis* from clinical specimens. The nutritional base is composed of beef

extracts, horse blood, niacin, and pancreatic digests. Charcoal and starch are added to neutralize inhibitors, especially fatty acids and peroxides that might be present in the medium. Cephalixin is the selective agent.

Inoculated plates should be incubated aerobically at 35°C in a moist environment for 5 to 7 days. *B. pertussis* colonies are domed, shiny, transparent, and tiny. The colonies are described as resembling mercury droplets. Regan-Lowe transport medium is also available. The transport medium differs from the isolation medium in that the transport medium uses lysed horse blood, whereas whole horse blood is used in the isolation medium. In addition, the transport medium contains one half as much charcoal as the isolation medium.

Salmonella-Shigella agar

Salmonella-Shigella (SS) agar is used to select for *Salmonella* and some strains of *Shigella* in stool specimens. SS agar is also differential in that these organisms produce characteristic colonies on the medium. SS agar contains bile salts, sodium citrate, and brilliant green, which inhibit the growth of gram-positive and many lactose-fermenting, gram-negative bacilli normally found in feces. Lactose is the sole carbohydrate source in the medium, and neutral red is the pH indicator. If an organism grows on the medium and ferments lactose, it will produce acid and change the indicator to pink-red. Sodium thiosulfate is added as a source of sulfur for the production of H₂S. If H₂S is produced, it reacts with the ferric ammonium citrate present in the medium, forming a black precipitate in the center of the colony.

A heavy inoculum of stool can be plated on SS agar because the formulation is so inhibitory; however, strains of *Shigella* may not grow on SS agar, and this medium should not be used as the sole primary plating medium when *Shigella* is a potential isolate. *Shigella* colonies appear colorless on SS agar because these organisms do not ferment lactose or produce H₂S. *Salmonella* colonies are colorless, with a black center, because these organisms usually make H₂S but do not ferment lactose. Pink to red colonies indicate that the organism ferments lactose; if there is a black center, it also produces H₂S. If *Proteus* grows on this medium, swarming is inhibited.

Schaedler agar

Schaedler agar is an enriched medium used for the isolation of anaerobic bacteria. Vegetable and meat peptones, yeast extract, and glucose provide the nutrients. The growth of more fastidious anaerobes is aided by the addition of vitamin K, sheep blood, and hemin. Facultative anaerobes also will grow on this medium, so aerotolerance testing should be performed on all isolated colonies to determine their oxygen dependency.

Selenite broth

Selenite broth is an enrichment broth used for the recovery of low numbers of *Salmonella* and some strains of *Shigella* from stool and other specimens containing large amounts of mixed

bacteria. The sodium selenite present in this medium inhibits the growth of many gram-negative bacilli and enterococci but permits the recovery of *Salmonella* and some *Shigella* species. Selenite is most effective at a neutral pH. Reduction of selenite during bacterial growth produces alkaline products that may inhibit the growth of salmonellae and also reduce the toxicity of the selenite for other organisms, so lactose and phosphate buffers have been included in this medium to maintain a neutral pH. Lactose fermenters produce acid, which neutralizes these alkaline products and returns the medium to a neutral pH.

Approximately 1 to 2 g of stool should be inoculated into the broth, which is then incubated at 35°C. The broth should be subcultured to enteric media after it has incubated for 12 to 18 hours (some references suggest 6 to 12 hours). Beyond this time frame, overgrowth with normal biota is likely because the inhibitory effect of the selenite decreases after 12 hours. A variation of the selenite broth formulation includes the addition of cystine to increase the recovery of *Salmonella*.

Sodium chloride broth, 6.5%

Sodium chloride broth is useful in the differentiation of streptococci. It primarily distinguishes *Enterococcus* spp. (positive) from group D streptococci (negative), both of which produce a positive bile-esculin reaction. In addition, viridans streptococci can be distinguished from *Enterococcus* (which may sometimes appear α -hemolytic) because the viridans streptococci, like group D streptococci, cannot grow in this medium.

Sodium chloride broth is prepared from heart infusion broth, a general-purpose medium that already contains 0.5% NaCl. NaCl is added to this medium to bring the salt concentration to 6.5%. Sodium chloride broth also contains glucose as a carbohydrate source, and some formulations add bromocresol purple, a pH indicator. If the organism can tolerate this high concentration of salt, it will grow in the medium and produce turbidity. Fermentation of glucose produces acid and can cause the medium to turn from purple to yellow if the pH indicator is present. Several colonies are inoculated into the broth and incubated overnight at 35°C. Any growth in the broth is considered positive, even if the indicator does not change color. To avoid a false-negative result, the broth should be gently mixed before interpretation. Inoculating the broth too heavily may give a false-positive result. Organisms other than enterococci, such as group B streptococci and aerococci, can produce positive results.

SP-4 broth and SP-4 agar

SP-4 broth and SP-4 agar serve as primary isolation media for *Mycoplasma* spp. SP-4 media contain yeast products that serve as growth factors for *Mycoplasma* and supply preformed nucleic acid. Fetal bovine serum supplies the cholesterol necessary for the synthesis of sterols for the bacterial membranes. Antimicrobials inhibit normal biota that may be present in the specimen. Penicillin is included to prevent the growth of gram-positive bacteria, amphotericin B inhibits fungi, and

polymyxin B inhibits gram-negative bacilli. Biphasic media provide microaerophilic and moist conditions, which some *Mycoplasma* spp. prefer.

Streptococcus-selective agar

Streptococcus-selective agar is a selective medium used to isolate streptococci, primarily to detect β -hemolytic streptococci in throat swabs. Columbia agar is the base to which ribonucleic acid and maltose are added to enhance the production of streptolysin S. Polymyxin B and neomycin are added to inhibit the growth of gram-positive and gram-negative organisms that are found as normal oral biota. Another formulation incorporates colistin and oxolinic acid to suppress the normal biota. Nonselective media (e.g., a blood agar plate) also should be inoculated with the specimen, and the growth on both plates should be compared.

Tetrathionate broth

Tetrathionate broth is an enrichment medium used for recovery of *Salmonella*, except serotypes Typhi and Arizonae, from stool specimens. Tetrathionate is produced when an iodine-potassium iodide solution is added to the basal broth. Bile salts in conjunction with thiosulfate and the iodine-iodide solution inhibit the growth of most gram-negative and gram-positive organisms, except *Salmonella*. Some formulations also include brilliant green or crystal violet, which increases the inhibitory nature of the medium. The medium must be used within 24 hours of preparation. Because the basal medium may be stored in the refrigerator indefinitely, some microbiologists prefer to dispense 10 mL of basal medium per tube. Just before use, 0.2 mL of iodine solution can be added to each tube. A heavy inoculum of stool can be added to the broth. After 12 to 24 hours of incubation at 35°C, the broth should be subcultured to enteric media to prevent overgrowth with normal biota. This medium inhibits most *Shigella* spp.

Thayer-Martin, modified agar

MTM agar is a selective enrichment medium used for recovering *N. gonorrhoeae* and *N. meningitidis* from specimens that have mixed microbiota. MTM agar is highly enriched to support the growth of the more fastidious *Neisseria* spp. A chocolate agar base and added growth factors such as hemoglobin, vitamins, diphosphopyridine nucleotide, L-cysteine, NAD, and glutamine are the main constituents of MTM. Corn starch also is included to absorb inhibitory substances that might be present. The modified formulation has less agar and glucose than the original Thayer-Martin medium. These changes seem to result in improved recovery of *Neisseria* spp.

MTM and Thayer-Martin media both contain antimicrobial agents that allow for the growth of pathogenic *Neisseria* spp. and prevent the growth of most other organisms. Both media contain vancomycin to inhibit the growth of gram-positive bacteria, colistin to inhibit gram-negative bacilli, and nystatin to prevent the growth of fungi. MTM differs from the original Thayer-Martin formulation by the addition of trimethoprim, which prevents *Proteus* spp. from swarming.

Martin-Lewis agar is a modification of the MTM formulation. In Martin-Lewis agar, anisomycin (20 μ g/mL) is substituted for nystatin as the antifungal agent. In addition, the vancomycin concentration (4 μ g/mL) is higher than in the MTM formulation. MTM plates should be incubated in a CO₂ incubator for several days. Because some strains of *N. gonorrhoeae* can be inhibited by vancomycin and trimethoprim, a CHOC plate should be used in conjunction with an MTM plate.

Thioglycollate broth, basal and enriched

Thioglycollate broth is an all-purpose medium that can be used to isolate a wide range of bacteria. It is often used along with culture plates when inoculating clinical specimens. In this case, it helps detect organisms present in low numbers, such as anaerobes, that are present in the original specimen. Formulations without glucose can be used in fermentation studies of anaerobes.

Nutrients are provided by the incorporation of casein, cysteine, glucose, and yeast extract. Thioglycollate, cystine, and sodium sulfite act as reducing agents in this medium, and the low concentration of agar prevents downward diffusion of oxygen, allowing for the growth of anaerobic organisms toward the bottom of the tube. Various supplements can be added for enrichment to support the growth of more fastidious organisms. These include hemin (5 μ g/mL), vitamin K (0.1 μ g/mL), and sodium bicarbonate (1 mg/mL), which can be autoclaved in the medium. Supplements that must be added after autoclaving include rabbit or horse serum (10% vol/vol) and Fildes enrichment (5% vol/vol), which are given as final concentrations in the medium. Thioglycollate broth should be stored at room temperature and then boiled and cooled before use. After inoculation of the clinical specimen, the medium is incubated at 35°C for 3 to 7 days and examined for turbidity. Smears for Gram stain should be made and compared with growth obtained on primary culture plates. If something different appears to be growing in the broth, subcultures should be performed. Bile salts can be added to make thioglycollate bile broth select for the growth of *Bacteroides fragilis* and *Clostridium perfringens* from clinical specimens.

Thiosulfate citrate bile salts sucrose agar

Thiosulfate citrate bile salts (TCBS) sucrose agar is a selective medium used to isolate *Vibrio* spp. from stool specimens. TCBS agar can also differentiate *Vibrio* spp. based on sucrose utilization. *Vibrio* spp. grow poorly on media designed for isolation of *Salmonella* and *Shigella* but produce colorless colonies on MAC. TCBS agar includes sodium citrate, sodium thiosulfate, and oxgall (10% solution equivalent to full-strength bile), which together inhibit many gram-positive cocci and gram-negative bacilli normally present in stool specimens. In addition, the high pH of TCBS agar encourages the growth of *Vibrio* spp. while inhibiting other organisms.

The ability of an organism to ferment sucrose is the basis for differentiating among various species of *Vibrio*. Bromothymol blue and, in some formulations, thymol blue are incorporated as pH indicators. *Vibrio cholerae* and *Vibrio alginolyticus* produce yellow colonies because they can ferment sucrose, whereas *Vibrio parahaemolyticus* and *Vibrio vulnificus* usually produce blue-green colonies because they do not ferment sucrose. Organisms that can produce H_2S from sodium thiosulfate have black centers because of the reaction of this gas with ferric citrate. *Vibrio* spp. do not produce H_2S . Oxgall and sodium cholate or bile salts (8 g/L) can be used in place of oxgall alone.

When using TCBS agar, a heavy inoculum should be applied because *Vibrio* spp. die quickly, and this medium is very inhibitory. A fresh specimen is best because these organisms are sensitive to dry conditions, sunlight, and acid pH. If there is a delay in plating, Cary-Blair semi-solid transport medium should be inoculated with the stool specimen rather than buffered glycerol transport medium. Plates should be incubated at 35°C for 18 to 24 hours and up to 48 hours. Oxidase testing cannot be performed on colonies isolated on TCBS agar. Occasionally, strains of *V. cholerae* produce blue-green colonies on this medium because of delayed sucrose fermentation. Some *Vibrio* spp. do not grow well on this medium. Also, other organisms, such as *Pseudomonas*, *Plesiomonas*, and *Aeromonas*, can grow on TCBS agar and usually produce blue colonies; therefore these must be distinguished from *Vibrio* spp.

Tinsdale agar

Tinsdale agar is a selective differential medium useful in isolating and identifying *C. diphtheriae* from specimens containing mixed biota. Tinsdale agar contains a high concentration of potassium tellurite, which inhibits the growth of most normal biota but permits *Corynebacterium* spp., especially *C. diphtheriae*, to grow. All *Corynebacterium* spp. growing on the medium produce gray to black colonies because of the reduction of tellurite to tellurium. In addition, *C. diphtheriae* colonies are surrounded by a brown halo. The brown halo is produced from the interaction of tellurite with the H_2S produced by the organism from cystine and thiosulfate. The basal medium can be stored indefinitely; tellurite and serum can be added just before use. Once prepared, the medium has a shelf life of 4 days.

When using Tinsdale agar, the plates are streaked for isolation, and the medium is stabbed in several areas. Sometimes browning occurs in these stabbed areas before it can be seen around surface colonies. Plates should be incubated at 35°C for 24 to 48 hours in ambient air. Increased CO_2 can slow down the production of the brown halo. It may require 48 hours for some *C. diphtheriae* strains to produce the characteristic halo. In addition, *Corynebacterium ulcerans* and *Corynebacterium pseudodiphtheriticum* also may produce a dark halo on this medium and must be differentiated from *C. diphtheriae*. Other organisms occasionally grow on Tinsdale agar. *Proteus* produces mucoid colonies and tends to blacken the medium. Rare streptococci and staphylococci can produce dark colonies with a surrounding halo but may be distinguished from the corynebacteria by performing a Gram stain.

Todd-Hewitt broth with gentamicin and nalidixic acid

Todd-Hewitt broth is used to grow streptococci for serotyping. Nutrients are provided by peptones and beef heart infusion, and glucose is added as an energy source. Throat swabs can be used to inoculate the broth that is then incubated at 35°C for 2 to 5 hours for serologic testing for detection of group A streptococci. The broth can be incubated for up to 24 hours then streaked for isolation on SBA plates. Pure cultures of β -hemolytic streptococci can be inoculated into the broth prior to serologic testing.

The selective formulation can be used to isolate group B streptococci from vaginal and rectal swabs. It can be used, however, to isolate many β -hemolytic streptococci from a clinical specimen that has mixed biota. Colistin and nalidixic acid (Lim broth) or gentamicin and nalidixic acid (Trans-Vag broth) can be added to inhibit the growth of gram-negative bacilli and select for group B streptococci. This broth is inoculated with the vaginal or rectal swab and incubated at 35°C for 18 to 24 hours. The broth is then subcultured to a blood agar plate, incubated for 24 hours at 35°C in 5% CO_2 , and examined for the presence of β -hemolytic colonies.

Triple sugar iron agar

Triple sugar iron (TSI) agar can be used to determine whether a gram-negative bacillus is a glucose fermenter or non-glucose fermenter, a fundamental characteristic in the initial classification of gram-negative rods. The medium also tests for sucrose and/or lactose fermentation, gas production during glucose fermentation, and H_2S production, all of which are useful in the differentiation of gram-negative rods belonging to the Enterobacteriales.

TSI agar contains glucose, sucrose, and lactose (fermentable carbohydrates); sucrose and lactose are each present at 10 times the glucose concentration. Other components include phenol red (pH indicator), peptone (carbon/nitrogen source), and sodium thiosulfate plus ferric ammonium sulfate (sulfur source and H_2S indicator, respectively). TSI agar resembles KIA except that TSI contains sucrose. Carbohydrate fermentation patterns resemble those of KIA; however, an acid (yellow) slant and acid (yellow) butt (A/A) in the TSI indicate that an organism ferments glucose and sucrose and/or lactose. Gas bubbles indicate gas produced from fermentation, and blackening indicates H_2S production, the same as in KIA. Precautions concerning the inoculation and incubation outlined in the KIA description also apply to TSI.

Trypticase soy agar

Trypticase soy agar (TSA) is an all-purpose medium that supports the growth of many organisms. It is frequently used as the basal medium for sheep blood agar plates. TSA contains peptones from soybeans and casein as a nutrient source and NaCl as an osmotic stabilizer. Agar serves as a solidifying agent. Unlike trypticase soy broth (TSB), TSA does not contain

glucose, which can interfere with the expression of β -hemolysis on sheep blood agar plates. Formulation with sheep blood and gentamicin added is used for the recovery of *Streptococcus pneumoniae*. Another formulation contains sheep blood and vancomycin to recover vancomycin-resistant enterococci.

Trypticase soy broth

TSB is an all-purpose medium that supports the rapid growth of most organisms, including streptococci, without added supplements. TSB contains soybean and casein digests as protein sources, NaCl for osmotic stability, glucose, and dipotassium phosphate as a buffer. Glucose fermentation can lower the pH causing acid-sensitive organisms such as *S. pneumoniae* to die at 24 hours of incubation. This broth is used as a medium in some blood culture bottles, sometimes to make an inoculum for Kirby-Bauer susceptibility testing, and as a medium for sterility testing. It should not be used for primary inoculation of clinical specimens.

Tryptophan broth, 1%

Tryptophan broth is used for performing the indole test, a procedure that is particularly useful in identifying species of Enterobacterales and identifying nonglucose-fermenting, gram-negative bacilli. This broth contains trypticase, a peptone rich in tryptophan, and NaCl, which serves as an osmotic stabilizer. Some bacteria possess the tryptophanase enzyme system, which hydrolyzes and deaminates tryptophan, producing indole, pyruvic acid, and ammonia. When Ehrlich or Kovac reagent is added to a tryptophan broth culture, indole produced by the organism reacts with the aldehyde portion of dimethylaminobenzaldehyde, the primary chemical in these reagents, and forms a red color.

Tryptophan broth should be inoculated with a few colonies from a pure culture and incubated for 24 hours at 35°C. Five drops of Kovac reagent are added to the medium; a red color in the reagent layer or at the interface of the reagent and broth signifies the presence of indole (positive). If Ehrlich reagent is used, 1 mL of xylene is first added to the broth culture at the end of the incubation period to extract indole. The tube is shaken, and five drops of the reagent are added. Kovac reagent is generally used when testing members of Enterobacterales, and Ehrlich reagent is used when testing nonglucose-fermenting, gram-negative bacilli and anaerobes. Other media have been developed to detect the production of indole from tryptophan: sulfide indole motility (SIM) agar, indole nitrate broth, and motility indole ornithine (MIO) medium. A rapid spot test using filter paper saturated with para-dimethylaminocinnamaldehyde reagent also has been used for indole determination. In this test, the organism is rubbed onto the surface of filter paper saturated with the spot indole reagent; the appearance of a blue color indicates a positive test.

Urea agar and broth

Urea media detect an organism's ability to hydrolyze urea. This is particularly useful in identifying species of

Enterobacterales. In these media, urea is hydrolyzed by the enzyme urease to form CO₂, water, and ammonia. The ammonia then reacts with components in the medium to form ammonium carbonate. This compound causes an increase in pH, which changes the pH indicator, phenol red, to pink. Neither the agar nor the broth formulations contain much protein, which prevents the formation of alkaline products from the breakdown of peptones and could result in false-positive results. The broth formulation contains monopotassium phosphate and disodium phosphate, which make the medium highly buffered. In addition, the broth formulation lacks glucose and peptone. Only organisms that are strong urease producers and not fastidious (e.g., *Proteus* spp.) will appear positive in this type of medium. The agar formulation is less buffered, so smaller amounts of urease activity can be detected. Also, glucose and peptone, which help support growth, are included.

The agar slant is inoculated with an inoculating loop or needle that has a small amount of the organism and incubated at 35°C for 18 to 24 hours. If urease is produced, the medium will turn pink. Rapid urease producers such as *Proteus* spp. turn the entire tube pink and may be detectable in a few hours. Slow urease producers, such as *Klebsiella*, only turn the slant pink. If the organism does not produce urease, there will be no color change. Stuart urea broth is incubated at 35°C for 18 to 24 hours. A positive reaction is red color throughout the broth.

Vaginalis agar

Vaginalis (V) agar is a selective or nonselective (depending on the addition of antimicrobial agents) enrichment medium useful in the isolation of *Gardnerella vaginalis*. V agar is a Columbia agar base with added peptone to provide nutrients, corn starch as an energy source, and human blood, rather than sheep blood, to detect hemolysis. *G. vaginalis* produces diffuse β -hemolysis only on media containing human blood. V agar can be made selective by the addition of colistin, nalidixic acid, and nystatin, which will inhibit many of the organisms that are found as normal vaginal biota.

Inoculated V agar plates are incubated in 5% CO₂ at 35°C. Plates can be observed at 24 hours, but often 48 to 72 hours is required for *G. vaginalis* to grow. The organism produces tiny dome-shaped, white colonies surrounded with zones of diffuse β -hemolysis.

Xylose-lysine-deoxycholate agar

Xylose-lysine-deoxycholate (XLD) agar is a selective, differential, primary plating medium used to isolate *Salmonella* and *Shigella* spp. from stool and other specimens containing mixed biota. *Salmonella* and *Shigella* spp. produce characteristic colonies on XLD, which aids in their recognition. XLD agar contains sodium deoxycholate, which inhibits gram-positive cocci and some gram-negative bacilli found in feces as normal biota. Because XLD agar has a lower concentration of bile salts than other formulations of enteric media, such as SS and HE agars, it is less selective but permits better recovery of *Shigella*. XLD agar contains three fermentable

carbohydrates—sucrose and lactose, which are present in high concentration, and xylose, which is present in a lower concentration. Phenol red is the pH indicator. The amino acid lysine is included to detect lysine decarboxylation. Sodium thiosulfate is a sulfur source from which organisms can make H_2S . Ferric ammonium citrate in the medium combines with H_2S to produce ferrous sulfide, a black precipitate.

Four types of colonies are produced on XLD agar. Yellow colonies are formed by organisms such as *E. coli* that ferment the excess carbohydrates to produce a large amount of acid and change the pH indicator to yellow. Because there is excess carbohydrate, these organisms do not decarboxylate the lysine, even though they can possess lysine decarboxylase. Bacteria that ferment only xylose and do not decarboxylate lysine also produce yellow colonies. Yellow colonies with black centers are organisms that ferment the excess carbohydrate and produce H_2S . Examples of organisms that produce this colony type are *Citrobacter* and some *Proteus* spp. *Shigella* and *Providencia*, which neither ferment xylose, lactose, or sucrose nor produce H_2S , produce colorless or red colonies. *Salmonella* and *Edwardsiella* produce red colonies with black centers. *Salmonella* and *Edwardsiella* ferment xylose to make acid, producing a yellow colony, but because xylose is present in limiting concentrations and is consumed, these organisms

will then decarboxylate the lysine to produce cadaverine, an alkaline product that causes the colony to revert to red. Blackening is caused by H_2S production.

XLD agar should be incubated at 35°C for 24 hours in ambient air. Some investigators have recommended incubating plates for up to 48 hours to enhance blackening in *Salmonella* colonies. With prolonged incubation, the delicate balance of this medium can be altered, and distinguishing normal biota from potential pathogens becomes more difficult. *Shigella dysenteriae* and *Shigella flexneri* can occasionally be inhibited on XLD agar. Some strains of *Salmonella* may fail to produce H_2S and therefore resemble *Shigella* colonies. On this medium, blackening is more likely to occur when alkaline conditions exist.

Selected mycology culture media and stains

Connie R. Mahon and Donald C. Lehman

Fungal media

A variety of enrichment and selective media is available to the clinical laboratory for the isolation and identification of pathogenic fungi. This appendix provides information about a select number of mycology media. Most media discussed in this appendix are commercially available in dehydrated or finished form. Recommendations regarding general use of the media, enrichment or selective, or combinations of each type, are outlined in Chapter 27 of this text.

Antifungal susceptibility testing media

The M27 and M38 Clinical and Laboratory Standards Institute (CLSI) documents describe the procedures for determining the susceptibility of yeasts and filamentous fungi to antifungal agents by broth dilution. Documents M44 and M60 describe antifungal disk diffusion and performance standards. The recommended medium for broth dilution is RPMI 1640 medium without sodium bicarbonate but with L-glutamine and glucose. 3-*N*-morpholinopropanesulfonic acid (MOPS) is added as a buffer to maintain the pH of the medium at 7.0. Yeast nitrogen base broth with 2% glucose also can be used for broth dilution procedures. Mueller-Hinton agar with 2% glucose and 0.5 µg/mL methylene blue dye is the recommended medium for disk diffusion testing.

Assimilation base for carbohydrates

Modified yeast nitrogen base is a synthetic basal medium that provides a sufficient source of nitrogen to support the growth of fungi during carbohydrate assimilation testing. Fungal isolates are plated for confluent growth, and carbohydrate disks are dispensed onto the surface to provide the specific carbohydrates for assimilation testing. The plates are incubated at 30°C for 48 to 72 hours and examined for growth around each disk. Good growth around a disk indicates assimilation

of that carbohydrate, whereas scant or no growth around a disk indicates no assimilation. Glucose (dextrose), used by all yeasts, serves as the growth control.

Alternatively, the basal media can be prepared as a broth to which individual carbohydrates are added in separate tubes. The yeast is inoculated into the series of tubes. The tubes are incubated, and the broth will become turbid if the yeast can assimilate the carbohydrate. The pattern of carbohydrate assimilation is used to identify yeasts.

Birdseed agar

Birdseed agar is a selective and differential enrichment medium designed for the isolation and preliminary identification of *Cryptococcus neoformans* and *Cryptococcus gatti*. The ground seeds (niger seeds) of *Guizotia abyssinica* provide enrichment as well as caffeic acid, which provides a substrate for the detection of phenol oxidase activity. On this medium, *C. neoformans* and *C. gatti* colonies typically display a tan to rich brown color because phenol oxidase activity results in the deposition of melanin in yeast cell walls. The colonies of other yeasts remain cream-colored. Chloramphenicol can be added to inhibit the growth of bacteria.

Bismuth sulfite–glucose–glycine yeast agar

Bismuth sulfite–glucose–glycine yeast (BiGGY) agar is a selective and differential medium for the isolation and differentiation of *Candida* spp. from clinical specimens. BiGGY contains yeast extract, glucose, glycine, bismuth ammonium citrate, and sodium sulfite. Yeast extract and glucose provide nutrients for growth. Glycine in high concentration is an additional nutrient and also inhibits many bacterial species. *Candida* spp. reduce bismuth salt to bismuth and sulfite to sulfide. Bismuth and sulfide combine to form a brownish to black precipitate that colors the colonies and also diffuses into the medium. *Candida albicans* forms brown to black colonies with no diffusible pigment. *Candida tropicalis* produces dark

brown colonies with black centers and a black diffusible pigment. Colony morphology for other *Candida* spp. can also be detected. Bismuth and sulfide compounds are also inhibitory to many bacterial species.

Brain-heart infusion agar (fungal formulation)

Brain-heart infusion (BHI) agar, fungal formulation, with 10% sheep blood is an enrichment agar useful for the isolation of pathogenic yeast and dimorphic fungi (in yeast form) from clinical specimens. The addition of antimicrobial agents (chloramphenicol and gentamicin or penicillin and streptomycin) makes the medium selective by inhibiting the growth of bacteria. The saprophytic fungi are not inhibited by these agents. Cycloheximide can be added to inhibit the saprobes.

Canavanine-glycine–bromothymol blue agar

This differential medium distinguishes *C. neoformans* from *C. gattii*. Plates are inoculated and incubated at 30°C for 1 to 5 days. *C. gattii* (serogroups B and C) colonies appear cobalt blue, indicating the assimilation of glycine, whereas colonies of *C. neoformans* (serogroups A and D) grow poorly and leave the medium greenish-yellow. Glycine is the sole carbon source; assimilation of glycine and the subsequent conversion of creatine to ammonia creates an alkaline shift in the pH, producing blue colonies. The medium is selective for *Cryptococcus* because they are the only yeasts known to have a natural resistance to L-canavanine. Bromothymol blue is added to indicate the shift in pH to 7.0 when the media appears cobalt blue.

Chromogenic agar for *Candida*

Chromogenic agars, produced by several manufacturers, provide rapid and accurate identification of *Candida* spp. isolated in clinical laboratories. Proprietary chromogenic substrates in the agar produce different colored products based on species-specific enzymes. CHROMagar *Candida* (BD Diagnostic Systems, Sparks, MD) incorporates chloramphenicol to inhibit bacteria; this medium is more selective than Sabouraud dextrose agar. *C. albicans* colonies are a yellow-green to blue-green, *C. tropicalis* appears dark blue to metallic blue, and *C. krusei* is a light mauve to mauve-colored colony. Colonies should be examined after a 48-hour incubation under aerobic conditions at 35°C. ChromID *Candida* agar (bioMérieux, Durham, NC) is another example.

Cornmeal agar

Variations of cornmeal agar are recommended for the cultivation or enhancement of particular fungal characteristics. Cornmeal agar without dextrose (glucose) is recommended for the cultivation of chlamydospore-bearing *C. albicans*, with chlamydospore production further enhanced by the addition of 1% Tween-80. This formulation also stimulates pseudohyphae and arthroconidia production. Cornmeal agar with 1% glucose is not recommended for chlamydospore production. Rather, this formulation favors more luxuriant growth and improves pigment production that is used to differentiate *Trichophyton rubrum*, which produces a red pigment, from *Trichophyton mentagrophytes*, which does not.

Each plate should be inoculated with a known *C. albicans* control and the unknown isolate(s) as single streaks without cutting into the agar; the streak lines should be covered with a flame-warmed coverslip. The coverslip provides a reduced oxygen environment that stimulates chlamydospore formation. The plate should be incubated at room temperature in the dark and examined with a low-power microscope lens daily for up to 1 week. Isolates may become positive for chlamydospores within 48 hours but cannot be considered negative before the fifth day of culture.

Dermatophyte test medium

Dermatophyte test medium is used to isolate dermatophytes from cutaneous specimens. Chloramphenicol and gentamicin are incorporated to inhibit the growth of most bacteria, and cycloheximide inhibits saprophytic fungi. This medium turns from yellow to red because of the formation of alkaline metabolites when dermatophytes grow. Phenol red is the pH indicator. The microscopic characteristics of the dermatophyte can be seen from the colonies growing on this medium. However, pigment production cannot be evaluated because of the pH indicator.

Inhibitory mold agar

This is an enriched selective medium for the growth of cycloheximide-sensitive fungi such as *Cryptococcus*, *Histoplasma capsulatum*, and the mucoraceous fungi. Chloramphenicol and gentamicin are used to inhibit most bacteria. Nutrients are provided by casein, yeast extract, and animal tissue.

Littman oxgall agar

Littman oxgall agar is a general-purpose medium used to isolate cycloheximide-sensitive fungi, especially dermatophytes. It is similar to inhibitory mold agar in that it does not contain cycloheximide. Glucose is added as a carbon source, peptone supplies a nitrogen source, and oxgall prevents the spreading of fungal colonies so yeasts and molds will form distinct colonies and can be isolated in pure culture. Crystal violet and streptomycin are added to inhibit the growth of bacteria.

Mycosel/mycobiotic agar

Mycosel (BD Diagnostic Systems) and Mycobiotic (Thermo Fisher Scientific, Waltham, MA) are selective media used to isolate pathogenic fungi, dermatophytes, and systemic pathogens. Nutrients are provided primarily from a pancreatic digest of soybean meal and glucose. The cycloheximide suppresses the growth of saprophytic fungi, whereas the chloramphenicol inhibits bacterial contaminants.

Potassium nitrate assimilation medium, modified

Potassium nitrate (KNO_3) assimilation medium is a differential medium useful in assessing the ability of yeasts to assimilate KNO_3 . The modified medium is a slanted medium containing KNO_3 , yeast carbon base, Nobel agar, and

bromothymol blue. A single colony of the cultured isolate is picked using a sterile applicator stick, inoculated over the entire slant surface, and incubated at 25° to 30°C. The ability to assimilate potassium nitrate is indicated by a color change of the medium from greenish yellow to blue or blue green.

Potato dextrose agar

Potato dextrose agar (PDA) is used as a primary plating medium for the cultivation, enumeration, and identification of yeasts and molds from products as well as from clinical specimens. The potato infusion encourages growth of and sporulation by fungi. Dermatophyte pigment production is enhanced on this medium. It is commonly used in the slide culture technique to visualize the microscopic morphology of fungi including mycelia and reproductive structures. Tartaric is added to lower the pH to approximately 3.5, inhibiting most bacterial species.

Potato flake agar

Potato flake agar is used to induce sporulation in fungi. It is easier to prepare and more stable than potato dextrose agar. Potato flakes and dextrose provide the nutrients. To enhance the growth of fungi and slightly inhibit bacterial growth, the pH is adjusted to approximately 5.6. A modified version incorporates cycloheximide and chloramphenicol to make the medium more selective for fungi, especially dermatophytes.

Rice extract agar

Rice extract agar without additional dextrose and with Polysorbate 80 is useful in the cultivation of *C. albicans*, with enhancement of chlamydospore production. Rice extract agar with 2% dextrose has been shown to enhance pigment production by *T. rubrum*, facilitating its differentiation from *T. mentagrophytes*.

The medium should be inoculated very lightly on the surface of the agar in a manner similar to that described for inoculation of cornmeal agar. The streaks should be covered with a flame-warmed coverslip to stimulate chlamydospore production. All cultures should be incubated at 25° to 30°C for 48 hours and then up to 10 days before regarding as negative.

Rice grains medium

Rice grains medium is useful in the differentiation of *Microsporum audouinii* from other dermatophytes, especially *Microsporum canis*. *M. audouinii* grows poorly on this medium and discolors the medium. Other dermatophytes and most other fungi grow well and sporulate on this medium, with no discoloration of the medium. Sterile rice grains should be spot-inoculated to prevent confusion when differentiating between discoloration and actual growth.

Sabouraud–brain-heart infusion agar

Sabouraud–brain-heart infusion agar (SABHIA) is a general-purpose medium used to isolate fungi. It is made from a combination of Sabouraud dextrose agar and brain-heart infusion agar. This medium is particularly useful for the isolation

of dimorphic fungi from clinical specimens. The addition of blood increases the isolation of dimorphic fungi and promotes the conversion to the yeast stage. Antimicrobials such as chloramphenicol, cycloheximide, streptomycin, and penicillin can be added to increase the selectivity of the medium for fungi.

Sabouraud dextrose agar or broth (Emmons modification)

Sabouraud dextrose agar and Sabouraud dextrose broth are nutrient media suitable for the cultivation of fungi, especially those associated with cutaneous and mucocutaneous infections. The formulations are identical, with the exception of the agar. To make solid plated medium, 1.5% to 2% agar is added to the broth formulation.

The Emmons-modified Sabouraud dextrose agar is the formulation commonly used today. It has 2% dextrose and a neutral pH as opposed to 4% dextrose and an acidic pH (5.6), which were in the original formulation developed by Sabouraud. Antimicrobials can be added to make this medium more selective for fungi.

Trichophyton agars 1 to 7

This set of seven media is used for the identification of *Trichophyton* species. The nutrients vary in the seven media. Based on a growth rating of 1 to 4 for each of the seven media, the fungus is identified.

Fungal mounting fluids

KOH-glycerin

Potassium hydroxide (KOH) or sodium hydroxide (NaOH) and glycerin solution are used as the mounting fluid in the preparation of wet mounts to visualize fungi in clinical material. The 10% or 20% KOH aids in clearing the specimen of nonfungal materials, and the glycerol retards the dissolution of the fungal elements. Nails may require a greater KOH concentration (25%). After the addition of the mounting fluid, the slide is set at room temperature for 5 to 30 minutes to allow digestion to occur. Historically, heating the slide was performed to speed up the clearing process of the KOH, but overheating has the potential of producing KOH crystals or damaging fungal elements. A modification of this procedure involves combining the KOH with 40% dimethyl sulfoxide (DMSO) rather than glycerol. The DMSO facilitates the penetration of KOH into the specimen materials and speeds the clearing process without the need for heating.

Lactophenol cotton blue

Lactophenol cotton (aniline) blue is a mounting medium useful for examining the microscopic morphology of an isolated fungus. It aids in staining hyphal elements (aniline blue) and preserving fungal materials (lactic acid), and it enhances visualization by staining all chitin-containing structures a light blue. A small drop of the mounting medium is placed onto a

slide; the fungal material is added directly and teased apart or placed on the surface of cellophane tape, topped with a coverslip, and examined. Some manufacturers add 10% polyvinyl alcohol as a fixative so permanent smears can be prepared.

Fungal stains

Ascospore stain

When grown on appropriate media, ascomycetous fungi can produce ascospores. A differential stain consisting of malachite green and safranin aids in visualizing ascospores, which stain green while the vegetative portion of the fungus stains red. A portion of the fungal growth is smeared onto a glass slide and heat-fixed. The slide is flooded with 5% malachite green for 3 minutes. The slide is washed with tap water and then decolorized for 30 seconds with 95% ethyl alcohol. The counterstain, 5% safranin, is added for 30 seconds. After air-drying, the slides are examined at 400× and 1,000× magnification.

Calcofluor white stain

The use of calcofluor white stain with 10% KOH enhances the visualization of fungi in clinical specimens of skin, hair, and nails. Fungal elements, including *Pneumocystis jirovecii*, take up the fluorescent dye because it binds to cellulose and chitin, which are found only in fungal cell walls and, depending on the combination of filters used, appear brilliant green-yellow or blue-white.

For examination of clinical samples, one drop of calcofluor white solution and one drop of 10% KOH are added to the specimen on a microscope slide. A coverslip is placed on top of the mixture, and the slide should sit for 5 to 10 minutes. Then the preparation is examined using a fluorescence microscope. The microscope must have a K532 excitation filter–BG 12 barrier filter or a G-35 excitation filter–LP420 barrier filter combination.

India ink

The India ink method is useful for demonstrating the presence of a capsule. It has been used for the demonstration of *C. neoformans* in clinical specimens, particularly cerebrospinal fluid. In this method, the capsule displaces the colloidal carbon particles in the ink; thus the capsule appears as a clear halo around the yeast cell. Because of the low sensitivity of the India ink method in detecting encapsulated yeast, antigen detection methods (e.g., latex agglutination, enzyme immunoassay) are recommended. However, some of these tests are prone to false-positive results.

Selected procedures

Donald C. Lehman and Connie R. Mahon

PROCEDURE 1

Acid-fast staining of mycobacteria

Principles

The primary stain binds to mycolic acid in the cell wall of mycobacteria, and similar organisms, and is retained after the decolorizing step with acid alcohol. The counterstain does not penetrate the mycobacteria to affect the color of the primary stain.

Application

The direct smear examination is a valuable diagnostic procedure for the detection of acid-fast organisms in clinical specimens.

Materials

TB auramine-rhodamine T stain
Carbolfuchsin stain
0.5% acid alcohol (0.5% HCl in 70% ethanol)
2% acid alcohol (prepared by laboratory)
1% sulfuric acid (partial acid-fast procedure)
0.5% aqueous potassium permanganate solution
0.3% aqueous methylene blue solution (prepared by laboratory)
Microscope slides 1 × 3 inches
Tap water

Procedures

Fluorescent stain

1. Cover smears with TB auramine-rhodamine T stain, and stain for 25 minutes.
2. Wash in running tap water.
3. Move slides to slide rack on acid alcohol collection container.
4. Flood smears with 0.5% acid alcohol, and decolorize for 2 minutes.
5. Wash smears in running tap water.
6. Move slides to original staining rack.
7. Flood smears with potassium permanganate counterstain for 4 minutes.
8. Wash smears in running tap water.
9. Air-dry.
10. Examine smears with the ×16 and ×40 objective lenses of a fluorescent microscope equipped with a filter system comparable to a BG-12 exciter filter and an OG-1 barrier filter. Examine each smear for 3 to 5 minutes.

Kinyoun stain

1. Cover smears with carbolfuchsin, and stain for 5 minutes.
2. Wash slides with running tap water.
3. Move slides to staining rack on acid alcohol collection container.
4. Decolorize with acid alcohol until no more color appears in the washings.
5. Wash slides with running tap water and move them to original staining rack.
6. Flood slides with methylene blue counterstain for 1 minute.

7. Wash with running tap water, drain, and air-dry.
8. Examine smears with ×100 oil immersion lens.

Modified Kinyoun stain (partial acid-fast)

1. Flood the slides with carbolfuchsin stain for 5 minutes.
2. Rinse with running tap water.
3. Flood slides with 70% ethanol, and rinse with tap water. Repeat until excess red dye is removed.
4. Move slides to rack on an acid collection container.
5. Continuously drop 1% sulfuric acid on the smear until the washing becomes colorless.
6. Rinse with running tap water.
7. Move slides to original staining rack.
8. Counterstain with methylene blue for 30 seconds.
9. Rinse with running tap water, and air-dry.
10. Examine smears with ×100 oil immersion objective lens.

Ziehl-Neelsen stain

1. Cover smear with a piece of filter paper cut slightly smaller than the slide.
2. Layer filter paper with carbolfuchsin stain. With a Bunsen burner, heat the smears gently until steaming occurs. Stain for 5 minutes without additional heating.
3. Proceed as for Kinyoun method, beginning with Step 2.

Results

Fluorescent stain

Mycobacteria stain bright orange. Count the number of acid-fast bacilli seen on the smear, and report as follows:

Number of acid-fast bacilli/oil immersion field (OIF)	Report
1–20	Number seen
21–80	Few
81–300	Moderate
>300	Numerous

Kinyoun and Ziehl-Neelsen stains

Mycobacteria stain red, whereas the background material and non-acid-fast bacteria stain blue. *Nocardia* spp. will weakly stain red in the modified Kinyoun stain. The coccidian species (*Cryptosporidium*, *Cystoisospora*, and *Cyclospora*) will also stain red.

Controls

Positive: *Mycobacterium tuberculosis*
Negative: *Bacillus subtilis*

PROCEDURE 2

Bacitracin susceptibility

Purpose

To differentiate *Streptococcus pyogenes* from other β -hemolytic streptococci

Principle

Group A streptococci are susceptible to low levels (0.04 units) of bacitracin, whereas other groups of β -hemolytic streptococci are resistant. Rare strains of group A streptococci are resistant (approximately 1%), whereas some strains of groups B, C, and G streptococci are susceptible (5% to 10%). Susceptibility to bacitracin presumptively identifies an isolate as *S. pyogenes*. This procedure was designed for use only with pure cultures; however, some clinical microbiologists will add a bacitracin disk to a primary throat culture to screen for *S. pyogenes*.

Specimen

Isolated colonies of test organism on sheep blood agar

Media

5% sheep blood agar plate

Reagent

Bacitracin disk, 0.04 units

Procedure

1. Streak surface of agar plate to obtain isolated colonies.
2. Aseptically place bacitracin disk onto inoculated surface. Press down gently on disk to ensure complete contact with agar surface.
3. Incubate plate at 35° C for 18 to 24 hours in a CO₂ incubator.

Interpretation

Susceptible: Any zone of inhibition around the bacitracin disk
Resistant: Uniform lawn of growth up to the edge of the disk (see Fig. 15.16)

Controls

Positive (susceptible): *Streptococcus pyogenes*
Negative (resistant): *Streptococcus agalactiae*

PROCEDURE 3

Bile esculin hydrolysis

Purpose

To differentiate group D streptococci and enterococci from other catalase-negative, gram-positive cocci

Principle

Group D streptococci and enterococci grow in the presence of bile, metabolize glucose, and also hydrolyze esculin to esculetin. Esculetin diffuses into the agar and combines with ferric citrate in the medium to produce a black complex.

Specimen

Isolated colonies of test organism on sheep blood agar

Media

Bile esculin agar

Procedure

1. Pick one or two isolated colonies from a sheep blood agar plate, and inoculate to bile esculin agar medium. A single plate can be divided into several pie-shaped sections for inoculation of multiple test organisms.

2. Incubate plate or slant at 35° C for 18 to 24 hours. A positive result is often seen within 4 hours. A negative result should be incubated for an additional 24-hour period.

Interpretation

Positive result: Blackening of the agar
Negative result: No blackening of the agar

Note: Growth alone does not constitute a positive result.

Controls

Positive: Group D streptococci
Negative: *Streptococcus pyogenes* or viridans streptococci

PROCEDURE 4

Bile solubility

Purpose

To differentiate *Streptococcus pneumoniae* from other α -hemolytic streptococci.

Principle

The bile (sodium deoxycholate) solubility test distinguishes *S. pneumoniae* from all other α -hemolytic streptococci. *S. pneumoniae* is bile-soluble, whereas all other α -hemolytic streptococci are bile-resistant. Sodium deoxycholate (2% in water) will lyse the pneumococcal cell wall. Bile salts, specifically sodium deoxycholate and sodium taurocholate, have the capability to lyse *S. pneumoniae* selectively when added to actively growing bacteria in agar or broth media.

Reagents

Sodium deoxycholate (10%)

Procedure

Plate spot test

1. Place 1 drop of 10% bile solubility reagent near suspected 18- to 24-hour-old colonies growing on sheep blood agar. Gently

rotate the agar plate, rolling the drop over several representative colonies. Take care not to dislodge the colonies.

2. Incubate the plate aerobically in an upright position at 35° C, and examine periodically for up to 30 minutes. Leave lid slightly ajar to enhance evaporation of the reagent.
3. Observe the colony for disintegration or solubility.

Interpretation

Positive result: Disintegration of colonies and/or the appearance of an α -hemolytic zone on the plate where the colony was located within 30 minutes.

Negative result: Colonies on the plate remain intact with no change in colony integrity within 30 minutes.

Controls

Positive: *Streptococcus pneumoniae*

Negative: α -Hemolytic or viridans streptococci

PROCEDURE 5

Calcofluor white stain

Principle

Calcofluor white (see [Appendix C](#)) is a colorless dye that binds to cellulose and chitin found in fungi. It fluoresces when exposed to long-wavelength ultraviolet and short-wavelength visible light. Special filters are required for optimal use. Evans blue is used as a counterstain and decreases fluorescence of host tissues and cells. Potassium hydroxide (KOH) can be added to clear the specimen of host material.

Application

Calcofluor white may be used as a specific stain for rapid screening of clinical specimens for fungal elements. This stain may be useful when morphology is ambiguous and the nonspecific staining of other techniques such as Gomori methenamine silver stain gives indeterminate results.

Materials

Stock solution

A 1% (wt/vol) aqueous solution of calcofluor white is prepared by dissolving the powder in distilled water with gentle heating. The stock solution is stable for 1 year at room temperature.

Working solution

0.1% calcofluor white M2R containing 0.01% to 0.08% Evans blue

Procedure

1. Place the specimen onto a glass microscope slide.
2. Add 1 to 2 drops of working calcofluor white solution. 1 drop of 10% KOH can be added to clinical specimens. If KOH is added, the slide can be gently heated to enhance tissue digestion.
3. Coverslip and let the specimen sit for 1 to 2 minutes.
4. Cover the slide with a paper towel, and gently press to remove any excess fluid.
5. Examine specimen on a fluorescent microscope, under $\times 10$ and $\times 40$ objective lenses using the following set of filters: G 365, LP 450, and FT 395.

Results

Yeast cells, pseudohyphae, and hyphae display a bright apple-green or blue-white fluorescence, depending on which barrier filter is used. *Pneumocystis* cysts, 5 to 8 μm , also fluoresce and exhibit a characteristic peripheral cyst wall staining with an intense internal "double-parenthesis-like" structure.

PROCEDURE 6

Calibration of the ocular micrometer

Purpose

To calibrate an ocular micrometer to determine the size of parasites and formed elements examined microscopically

Principle

Size is an important criterion in the identification of parasites, especially those found in clinical specimens from the digestive tract. Calibrating an ocular micrometer allows laboratory scientists to determine the size of objects seen during a microscopic examination of clinical material.

Procedure

1. Insert the ocular micrometer into the eyepiece of the microscope so the zero of the scale is on the left side.
2. Place the calibrated stage micrometer on the stage, and focus on the scale using the low-power ($\times 10$ objective) lens. The stage micrometer is divided into major lines separated by 0.1 mm ($100\mu\text{m}$) and minor lines separated by 0.01 mm ($10\mu\text{m}$).
3. While using low power, align the zero on the left side of the stage micrometer with the zero on the left side of the ocular micrometer. Do not move the stage micrometer after this step.

4. Scan the two scales for a point where a division line on the ocular micrometer directly aligns with a division line (minor line) on the stage micrometer.
5. Count the number of stage units and ocular units at this point. Divide the number of stage units by the number of ocular units, and multiply the result by 10. This gives the value (in micrometers) for 1 ocular unit on low power.

$$\text{Micrometers/ocular unit} = \left(\frac{\text{No. of stage units}}{\text{No. of ocular units}} \right) \times \left(\frac{10\mu\text{m}}{\text{Stage unit}} \right)$$

6. Repeat the procedure at high power ($\times 40$ objective lens) and with the $\times 100$ objective lens to get the value of one ocular unit at each of these magnifications. To calculate the size of an organism, count the number of ocular units, multiply by the value for an ocular unit at that magnification, and report the value in micrometers.

PROCEDURE 7

CAMP test

Purpose

To differentiate *Streptococcus agalactiae* (group B *Streptococcus*) from other β -hemolytic streptococci

Principle

S. agalactiae produces CAMP (named after Christie, Adkins, Munch-Peterson) factor, which enhances the lysis of sheep red blood cells by staphylococcal β -lysin. A positive reaction can be observed in 5 to 6 hours with incubation in CO_2 (18 hours with incubation in ambient air).

Specimen

1. Isolated colonies of test organism on sheep blood agar
2. β -Lysin-producing *Staphylococcus aureus* on sheep blood agar

Medium

Sheep blood agar plate

Procedure

1. Inoculate *S. aureus* along a straight line down the center of the agar plate.

2. Inoculate the streptococcal isolates along a thin line about 2 cm long and perpendicular to, but not touching, the *S. aureus* streak.
3. Incubate plate at 35°C for 18 hours.

Interpretation

Positive result: Arrowhead-shaped area of enhanced hemolysis where the two streaks (staphylococcal and streptococcal) approach each other (see Fig. 15.17)

Negative result: No enhanced hemolysis

CAMP inhibition reaction (reverse CAMP-positive): Inhibition of hemolysis by *S. aureus* where the two streaks approach each other

This reaction is characteristic of *Arcanobacterium haemolyticum* caused by a phospholipase D.

Controls

Positive: *Streptococcus agalactiae*

Negative: *Streptococcus pyogenes*

PROCEDURE 8**Catalase test****Purpose**

To differentiate organisms that produce the enzyme catalase from those that do not produce catalase

Principle

Staphylococci produce an enzyme, catalase, which reacts with peroxide to liberate oxygen. When a colony is emulsified in 3% hydrogen peroxide, the resultant bubbles on the slide can be visualized, which constitutes a positive test result.

Reagent

3% Hydrogen peroxide

Procedure

1. Place 1 drop of hydrogen peroxide on a clean glass slide.

2. Pick the colony in question from an agar plate with a wooden applicator stick.
3. Touch the stick containing the bacteria to the drop of hydrogen peroxide, and observe for immediate bubbling. The reaction is positive if there is a rapid evolution of gas.

Note: The enzyme catalase is present in red blood cells. Colonies to be tested should not be taken directly from a blood agar plate.

Interpretation

Positive result: Bubbling

Negative result: No bubbling

Controls

Positive: *Staphylococcus aureus*

Negative: *Streptococcus pyogenes*

PROCEDURE 9**Coagulase test (tube)****Purpose**

To differentiate and identify staphylococcal species that produce the enzyme coagulase

Principle

The tube coagulase test detects the presence of free coagulase enzyme produced by *S. aureus*. This extracellular enzyme forms a clot when a bacterial suspension is incubated with plasma. The screening test by the slide method detects only cell-bound coagulase; therefore any negative slide coagulase test must be confirmed with the tube coagulase test.

Specimen

A broth culture of the organisms to be tested or a single colony from a blood agar plate

Reagent

Coagulase plasma (BD BBL; Becton Dickinson, Franklin Lakes, NJ)

Procedure

1. To 0.5 mL of undiluted rabbit plasma, add 1 loopful of growth from 18- to 24- hour agar culture, 0.1 mL of broth culture, or a single colony from a blood agar plate.
2. Incubate in a heating block at 35° C, and examine for clotting at 30-minute intervals for 4 hours.

3. If no clot is observed at the end of 4 hours, let stand at room temperature for 18 to 24 hours. Observe for clotting.

Interpretation

A positive coagulase test result is represented by any degree of clotting from a loose clot suspended in plasma to a solid clot. The majority of coagulase-positive strains produce a clot within 4 hours.

Notes

1. A false-positive test result may occur with mixed cultures or with a pure culture of a gram-negative bacillus, but the clotting mechanism is different. Therefore organisms to be tested must first be determined to possess characteristics consistent with the genus *Staphylococcus*.
2. *S. aureus* also produces the fibrinolysin enzyme staphylokinase, which lyses the clot. It is important to examine for a clot after 4 hours of incubation, or a false-negative result can occur.

Controls

Positive: *Staphylococcus aureus*

Negative: *Staphylococcus epidermidis*

PROCEDURE 10

Corn Meal Agar for yeast identification

Purpose

To aid in the identification of pathogenic yeasts by microscopic morphology

Principle

Isolated yeasts are inoculated onto the surface of a Corn Meal agar with Polysorbate (tween) 80 plate (see [Appendix C](#)). The inoculum is covered with a coverslip and incubated for 3 days. The yeasts on the plate are examined microscopically. Microscopic morphology is an important characteristic in the identification of yeasts.

Specimen

Isolated cultures of yeasts

Medium

Corn Meal Agar with Tween 80 plate; one third or one fourth of a plate can be used for each yeast.

Procedure

1. Pick up a small amount of a yeast colony with an inoculating loop.

2. Make one streak of the yeast in the center of the agar surface. Do not cut the agar.
3. Make three or four streaks across the original streak to dilute the inoculum, being careful not to cut into the agar. Stab the medium twice through a streak line being careful not to touch the bottom of the Petri dish.
4. Cover the inoculum with a sterile coverslip, and incubate at room temperature in the dark for 2 days. If the results are negative, reincubate an additional 48 to 72 hours.
5. Remove the lid from the Petri dish, and examine the yeast with the low-power (×10) and high-power (×40) objective lenses for the presence of hyphae, pseudohyphae, arthroconidia, chlamydoconidia, and blastoconidia.

Controls

Candida albicans is used to demonstrate hyphae and chlamydospores.

Cryptococcus spp. are used to demonstrate blastoconidia.

PROCEDURE 11

Germ tube production for yeast identification

Purpose

To differentiate among the pathogenic yeast based on the ability to produce a germ tube

Principle

When grown in serum or plasma at 35° C, some yeasts form hyphae. This is an important characteristic in the identification of *Candida albicans*.

Specimen

Isolated cultures of yeasts

Medium

Rabbit plasma or serum or fecal calf serum

Procedure

1. Make a light suspension by adding one yeast colony to 0.5 mL of sterile serum. Remel Germ Tube Solution (Thermo Fisher Scientific, Waltham, MA), composed of fetal bovine serum and

trypticase soy broth, may be used as an alternative. This alternative substrate eliminates the risk of human immunodeficiency virus and hepatitis viruses that can be present in human serum.

2. Incubate the suspension at 35° C for 2.5 to 3 hours.
3. Place 1 drop of the suspension on a glass microscope slide, and add a coverslip.
4. Observe microscopically for the presence of germ tubes. Hyphae budding from a yeast cell without a constriction is a true germ tube. If there is a constriction at the point of budding, that is a pseudogerm tube.

Controls

A known germ tube positive isolate of *C. albicans* can serve as the positive control; *Cryptococcus* spp. can be used as a negative control.

PROCEDURE 12

Gram stain

Principles

The Gram staining method was developed by the Danish bacteriologist Christian Gram in 1884. The sequential steps provide for crystal violet (hexamethyl-*p*-rosaniline chloride) to color all cells and background material a deep blue and for Gram's iodine to provide the larger iodine element to replace the smaller chloride in the stain molecule. Bacteria with thick cell walls containing teichoic acid retain the crystal violet-iodine complex dye after decolorization and appear deep blue; they are *gram-positive bacteria*. Other bacteria with thinner walls containing lipopolysaccharides do not retain the dye complex; they are *gram-negative bacteria*. The alcohol-acetone decolorizer damages these thin lipid walls and allows the stain complex to wash out. All unstained elements are subsequently counterstained red by safranin dye. The differential ability of the Gram stain makes it useful in microbial taxonomy.

Application

The Gram stain is used routinely in the clinical microbiology laboratory for the primary microscopic examination of specimens submitted for smear and culture. It is ideally suited for specimen types in which bacterial infections are strongly suspected, but it may be used to characterize any specimen. Cerebrospinal fluid, sterile fluids, expectorated sputum or bronchoalveolar lavages, and wounds and exudates are routinely stained directly. The Gram stain is regularly used to characterize bacteria growing on culture media.

Materials

Crystal violet
Gram's iodine solution
Decolorizer (95% ethanol or 1 : 1 ratio of acetone and 95% ethanol)
Safranin
Microscope slides 1 × 3 inches
Tap water

Procedure

1. Dry the material on the slide so it does not wash off during the staining procedure. Adherence can be improved by fixation in 70% to 95% alcohol or by gently warming the slide (heat fixation) to remove all water from the material.
2. Place the smear on a staining rack, and overlay the surface of the material to be stained with the stains in sequence as shown in the figures.
3. Place the smear in an upright position in a staining rack, allowing the excess water to drain off and the smear to dry. Never blot a critical smear (e.g., cerebrospinal fluid). Never put immersion oil on a smear until it is completely dry.
4. Examine the stained smear using the low-power objective lens, and select an area to examine more closely using a ×40 to ×100 oil objective lens. Suspicious areas are evaluated using the ×100 oil objective lens of the microscope.

Results

Gram-positive bacteria stain dark blue to blue-black. All other elements stain red with safranin. Individual structures absorb a different amount of safranin, so some have prominent staining (strong avidity), and others are weakly stained (low avidity). Among the gram-negative bacteria, the enterics have strong avidity and stain bright red; pseudomonads are less avid and stain moderately well. Anaerobic bacilli and other thin-walled gram-negative organisms, such as *Borrelia*, *Legionella*, and *Spirillum* spp., stain weakly. Always check the quality of the stain and the results of the quality control organisms before interpretation. Basic fuchsin (0.1%) is sometimes used as a counterstain to enhance visualization of weakly staining gram-negative bacteria.

Precautions

The Gram stain reaction may vary from the expected in numerous well-recognized circumstances. If the crystal violet is rinsed too vigorously before it is complexed with the iodine, it will wash away and leave poor or no staining of gram-positive organisms. If the decolorization is too vigorous or prolonged, the gram-positive complex will be removed, and the normally gram-positive organisms will not stain blue. If the decolorization is insufficient, organisms may be falsely

interpreted as gram-positive, and organisms in the thicker areas of the sample may be obscured. If the safranin is left on the slide for a prolonged period (minutes), the gram-positive complex will be leached from the positive cells; however, failure to leave the safranin in place for sufficient time will result in failure to stain gram-negative bacteria and background materials. Gram stain characteristics may be atypical in antimicrobial-treated and dead or degenerating organisms. Typical morphotypes should be sought. Any sample that raises questions about the quality of the stain or the method should be restained.

The crystal violet stain is not bound into the organism until the iodine is added. Any rinsing between the crystal violet and the iodine steps must be very brief.

Flood the slide with crystal violet, and allow it to stand for 30 seconds.

The dilute iodine solution can be used to wash away the crystal violet, and no water rinse is employed.

Flood with Gram's iodine, and allow it to stand for 30 to 60 seconds.

Decolorize the slide with a 1 : 1 mixture of the two decolorizers, acetone and 95% ethanol, and wash immediately with water. Acetone is a more rapid decolorizer and may give better results, but the reaction must be stopped with water as soon as the purple color disappears.

Flood with safranin or 0.1% basic fuchsin for 30 seconds to 1 minute (anaerobes). The counterstain must not be left in place for too long. Anaerobes may stain better at 1 minute or with carbol-fuchsin. Rinse very lightly with water.

Check the staining reactions of quality control organisms before proceeding with smear interpretation.

Controls

Gram positive: *Staphylococcus aureus*
Gram negative: *Escherichia coli*

PROCEDURE 13

Hippurate hydrolysis test

Purpose

To differentiate *Streptococcus agalactiae* (group B *Streptococcus*) from other β -hemolytic streptococci

Principle

The enzyme hippuricase hydrolyzes hippuric acid to form sodium benzoate and glycine. Subsequent addition of ninhydrin results in the release of ammonia from the oxidative deamination of the α amino group in glycine as well as the reduced form of ninhydrin, hydrindantin. The ammonia reacts with residual ninhydrin and hydrindantin to produce a purple-colored complex. Some isolates of group D streptococci also hydrolyze hippurate; however, these isolates are less likely to be β -hemolytic; therefore their colony morphology is different from that of group B *Streptococcus*. An isolate that is hippurate positive and bile esculin negative has a very high probability of being *S. agalactiae*.

Specimen

Isolated colonies of test organism on sheep blood agar

Reagents

Sodium hippurate, 1%

Sodium hippurate: 1 g

Distilled water: 100 mL

Dispense 0.5-mL aliquots into small capped vials. Store at -20°C . Storage life is 6 months.

Ninhydrin reagent

Ninhydrin: 3.5 g

Acetone-butanol mixture (1 : 1): 100 mL

Store at room temperature. Storage life is 12 months.

Procedure

1. Inoculate the solution of sodium hippurate heavily with colonies 18 to 24 hours old until a milky suspension is obtained.
2. Incubate tube for 2 hours at 35°C .
3. Add 0.2 mL of ninhydrin reagent.
4. Mix and incubate for 10 to 15 minutes at 35°C .

Interpretation

Positive result: Deep purple color—indicates hippurate hydrolysis

Negative result: No color change or very slight purple color

Controls

Positive: *Streptococcus agalactiae*

Negative: *Streptococcus pyogenes*

PROCEDURE 14

Leucine aminopeptidase

Purpose

To differentiate and identify catalase-negative, gram-positive cocci such as *Aerococcus* and *Leuconostoc* from *Streptococcus*, *Enterococcus*, *Lactococcus*, and *Pediococcus*.

Principle

Based on the ability of catalase-negative, gram-positive cocci to hydrolyze leucine- β -naphthylamide by the enzyme leucine aminopeptidase (LAP) produced by LAP-positive organisms. The enzymatic activity releases β -naphthylamine, which when p-dimethylaminocinnamaldehyde reagent is added forms a highly visible red color.

Reagents

Remel LAP Disc w/Reagent (Thermo Fisher Scientific)

Procedure

1. Aseptically place a LAP disk in a sterile petri dish, and allow it to warm to room temperature.

2. Slightly dampen the LAP disk with reagent grade water or with a small amount of sterile distilled water.
3. Using a wooden applicator stick, rub a small amount of several colonies of an 18-to-24-hour pure culture onto a small area of the LAP disk.
4. Incubate at room temperature for 5 minutes.
5. After the incubation period, add 1 drop of cinnamaldehyde reagent, and read within 1 minute.

Interpretation

Positive result: Development of a red/pink color

Negative result: No change or a slight yellow color

Controls

Positive: *Enterococcus faecalis*

Negative: *Aerococcus viridans*

PROCEDURE 15

NALC-sodium hydroxide digestion-decontamination

Purpose

To enhance the recovery of mycobacteria from clinical specimens by reducing the number of contaminating or commensal bacteria

Principle

Sodium hydroxide (NaOH) acts as both a decontaminating agent and digestant. Because of the toxicity of NaOH to mycobacteria, the agent should be used at the lowest concentration that inhibits the growth of contaminating bacteria. *N*-acetyl-L-cysteine (NALC) is a mucolytic agent that allows for a lower concentration of NaOH to be used and thereby optimizes the recovery of mycobacteria from the specimen. Decontamination should only be done on specimens likely to be contaminated with normal microbiota, such as sputa.

Reagents

NALC-NaOH digestant: Combine equal volumes of 2.94% sodium citrate dihydrate (0.1 M) and 4% NaOH. Just before use, add 0.5 g of powdered NALC/100 mL of mixture. Refrigerate when not in use; discard after 24 hours.

Phosphate buffer (0.067 M, pH 6.8) or sterile, distilled water, 30 to 40 mL per specimen

Bovine albumin fraction V, 0.2% in sterile saline

Procedure

1. Working in a biological safety cabinet, transfer 10 mL of the specimen (or total specimen, if volume is less than 10 mL) to a 50-mL, screw-capped centrifuge tube. If the specimen volume is greater than 10 mL, select the most purulent-appearing material. Add an equal volume of NALC-NaOH digestant to each sample.
2. Tighten caps and mix on a vortexer until liquefied (5 to 20 seconds), inverting each tube to ensure that the NALC-NaOH

solution contacts any untreated particles on the upper part of the tube.

3. Let the tubes stand at room temperature for 15 minutes. If more decontamination is desired, increase the concentration of NaOH rather than the time the specimen is exposed to the digestion-decontamination mixture.
4. Dilute the digested-decontaminated specimens to the 50-mL mark with sterile distilled water or sterile phosphate buffer to minimize the continuing action of the NaOH and lower the specific gravity of the specimen. Tighten caps, and invert or swirl to mix.
5. Centrifuge at $\times 3000g$ for 15 minutes (or the appropriate combination of relative centrifugal force and time to give 95% sedimentation) using aerosol-free safety cups or in an aerosol-controlled vented refrigerated centrifuge.
6. Holding the tube so the sediment is on the upper side of the tube, pour off the supernatant into a splashproof discard container of disinfectant.
7. Holding the tube in a horizontal position to keep the sediment as dry as possible, use a sterile applicator stick to remove a small part of the sediment, and place it on a marked microscope slide. The smear should be about 1×2 cm.
8. Resuspend sediment in 1 to 2 mL of sterile 0.2% bovine albumin solution. If the medium will be inoculated immediately, the sediment may be resuspended in sterile water or sterile saline.
9. An optional step is to prepare a 1:10 dilution using 0.5 mL of the resuspended sediment in 4.5 mL of sterile water. Dilution decreases the concentration of toxic substances that may inhibit the growth of mycobacteria. Inoculate diluted and undiluted specimens to solid media.

PROCEDURE 16

Novobiocin susceptibility test

Purpose

To differentiate *Staphylococcus saprophyticus* from other coagulase-negative staphylococci (CoNS)

Principle

S. saprophyticus is a significant isolate in urine samples of women. *S. saprophyticus* must be differentiated from other CoNS such as *S. epidermidis*. *S. saprophyticus* is resistant to a 5- μ g novobiocin disk, whereas other CoNS are susceptible.

Note: Other CoNS that are resistant to 5- μ g novobiocin are *S. xylosus*, *S. cohnii*, and *S. sciuri*, but they are uncommon isolates from the urine.

Reagents

BBL Taxo Differentiation-Disc Novobiocin 5- μ g (BD Diagnostics, Sparks, MD)

Procedure

1. Prepare a suspension of the unknown *Staphylococcus* sp. in saline equal to a McFarland 0.5 standard.

2. Using a swab, inoculate the entire surface of a Mueller-Hinton plate in three directions. Allow the inoculum to dry with lid in place for 5 minutes.
3. Place a 5- μ g novobiocin disk at the center of the inoculum. Repeat the procedure using the positive and negative controls.
4. Incubate the cultures at 35° C in an ambient incubator for 18 to 24 hours.
5. After 18 to 24 hours of incubation, determine if the test organism is susceptible (≥ 16 mm) or resistant (< 16 mm).

Interpretation

≥ 16 mm = susceptible

< 16 mm = resistant

Controls

Susceptible: *Staphylococcus epidermidis*

Resistant: *Staphylococcus saprophyticus*

PROCEDURE 17

Optochin susceptibility test

Purpose

To differentiate *Streptococcus pneumoniae* from other α -hemolytic streptococci

Principle

The optochin susceptibility test is based on the differential susceptibility of *S. pneumoniae* and other hemolytic streptococci to ethyl hydroxycupreine hydrochloride. *S. pneumoniae* is inhibited by less than 5 mg/mL of this agent. When contained within a paper disk and applied to an agar surface, as for the disk diffusion antimicrobial susceptibility test, the inhibitory zones obtained with *S. pneumoniae* significantly exceed those obtained with other α -hemolytic streptococci.

Reagents

The Optochin Disc and the BBL Taxo P Disc (BD Diagnostics) are impregnated with ethyl hydroxycupreine hydrochloride (5 μ g per disk).

Procedure

1. Streak suspicious colonies on a sheep blood agar plate covering an area 3 cm in diameter.
2. Place an optochin disk in the center of the streaked area, pressing gently with sterile forceps.
3. Invert the plate, and incubate at 35° for 18 to 24 hours. After incubation, measure the zone of inhibition around the disk.

Interpretation

Zone diameter of inhibition >15 mm, *S. pneumoniae*
Zone diameter of inhibition <15 mm, α -hemolytic *Streptococcus viridans* group

Controls

Positive: *Streptococcus pneumoniae*
Negative: α -Hemolytic *Streptococcus viridans* group

PROCEDURE 18

Oxidase test

Purpose

To identify organisms that produce the enzyme cytochrome oxidase

Principle

Neisseria spp. and some gram-negative rods produce indophenoloxidase, which becomes pink to dark red and finally black when colonies contact the oxidase reagent.

Specimen

Isolated bacterial colonies growing on sheep blood or chocolate agar plates

Reagents

Oxidase reagent, 1% aqueous solution of N,N,N',N' tetramethyl-para-phenylenediamine dihydrochloride (TMPD). Available as a commercial, ready-to-use preparation. Cepti-Seal Oxidase Reagent (BD BBL and BD Difco), or disks

Procedure

1. Place 2 to 3 drops of reagent on a piece of Whatman no. 1 filter paper.

2. Remove a suspected colony from the plate with a sterile applicator stick, and smear onto the reagent saturated paper.
3. Observe for color changes.
4. Microorganisms are oxidase positive when the color changes to dark purple within 5 to 10 seconds.

Note: Microorganisms are delayed oxidase positive when the color changes to purple within 60 to 90 seconds. The modified oxidase test for gram-positive cocci uses 6% TMPD in dimethyl sulfoxide.

Interpretation

An oxidase-positive reaction is a purple color on the filter paper in 5 to 10 seconds.
Microorganisms are oxidase negative if the color does not change or it takes longer than 2 minutes

Controls

Positive: *Pseudomonas aeruginosa*
Negative: *Escherichia coli*

PROCEDURE 19

δ -aminolevulinic acid porphyrin test (disk method)

Purpose

To differentiate *Haemophilus* spp. that require exogenous X factor (hemin) for growth

Principle

Based on the ability of *Haemophilus* spp. to synthesize protoporphyrin intermediates in the synthesis of heme from the substrate δ -aminolevulinic acid (ALA). *Haemophilus* spp. that require exogenous X factor (hemin) for growth are not capable of synthesizing protoporphyrins from ALA, hence are negative with this test. Species that do not require exogenous X factor for growth possess the enzymes that convert the substrate ALA to protoporphyrin compounds and are therefore ALA-porphyrin test positive. The porphyrin test can be performed in agar, in broth, or on a disk.

Reagents

Commercially available ALA-impregnated filter paper disks (Thermo Fisher Scientific)

Procedure

1. Place the disk in a sterile petri dish. Moisten the disk with sterile water.
2. Using a sterile loop or applicator stick, inoculate the disk with the organism from a pure 18- to 24-hour growth culture medium.
3. Incubate in ambient air at 35° C for up to 6 hours. After 6 hours, observe the disk under an ultraviolet light (Wood's light).

Interpretation

Brick-red fluorescence in the area of inoculation indicates a positive test result. These *Haemophilus* spp. can produce hemin and therefore do not require it in culture media. No fluorescence is a negative test result.

Controls

Positive: *Haemophilus parainfluenzae*
Negative control: *Haemophilus influenza*

PROCEDURE 20**L-Pyrrolidonyl α -naphthylamide hydrolysis test****Purpose**

To differentiate gram-positive cocci that hydrolyze the substrate L-pyrrolidonyl α -naphthylamide (PYR) from those that are PYR-negative

Principle

PYR-impregnated disks serve as the substrate to produce α -naphthylamine, which is detected in the presence of D-dimethylaminocinnamaldehyde (DMCA) by the production of a red color.

Specimen

Isolated colonies of test organism on sheep blood agar

Procedure

1. Lightly moisten a PYR-impregnated disk with sterile water.

2. Using a sterile loop or wooden applicator stick, rub one or more isolated colonies onto the surface of the disk.
3. **Note:** Incubation time and temperature vary slightly by manufacturer. Incubate disk as indicated in the manufacturer's instructions, generally 2 to 15 minutes.
4. Add 1 drop of color developer, and observe for a red color on the disk within 5 minutes.

Interpretation

Positive result: Red color

Negative result: Colorless

Controls

Positive: *Enterococcus faecalis*

Negative: *Streptococcus agalactiae*

PROCEDURE 21**Salt tolerance test****Purpose**

To differentiate gram-positive cocci that grow in 6.5% NaCl from those that are inhibited by this salt concentration

Principle

Enterococcus, *Aerococcus*, and some species of *Pediococcus* and *Leuconostoc* can withstand a higher salt concentration than other gram-positive cocci.

Specimen

Isolated colonies of test organism on sheep blood agar

Medium

6.5% NaCl broth, nutrient broth base

Procedure

1. Pick one or two isolated colonies from a sheep blood agar plate and lightly inoculate 5 mL of NaCl broth.
2. Incubate broth at 35° C for 3 days. Check daily for growth.

Interpretation

Positive result: Turbidity

Negative result: No turbidity

Controls

Positive: *Enterococcus faecalis*

Negative: *Streptococcus pyogenes* or viridans streptococci

PROCEDURE 22**Slide culture for the identification of fungi****Purpose**

To aid in the identification of molds by microscopic appearance

Principle

Isolated fungi are inoculated onto a block of agar lying on a microscope slide. The agar block is covered with a coverslip and incubated until mature growth of the fungus is noted. The coverslip is removed, and the material attached to the coverslip is stained and examined microscopically. Microscopic morphology is an important characteristic in the identification of fungi, particularly molds.

Specimen

Isolated cultures of test fungi

Medium

Potato dextrose agar or similar fungal medium

Procedure

Prepare slide cultures in a biological safety cabinet. Fungi suspected of being pathogens are not recommended for observation in slide cultures.

1. Place a piece of filter paper into the bottom of a 100-mm sterile Petri dish.

2. Place a bent glass rod, two pieces of plastic tubing, or the bent end of a flexible straw on the filter paper.
3. Lay a clean, flamed, glass microscope slide on top of the bent glass rod, two pieces of plastic tubing, or the bent end of a flexible straw.
4. Cut a 1-cm $\times$ 1-cm square block of fungal medium, such as potato dextrose agar, from a Petri dish, and aseptically transfer the block to the microscope slide.
5. Inoculate the four sides of the agar block with the test fungus by using a heavy-gauge teasing needle or a sterile wooden applicator stick.
6. Cover the block with a flamed sterile coverslip.
7. Moisten the filter paper with sterile water and place the lid on the Petri dish.
8. Incubate the slide culture at room temperature (22° C). Examine the culture periodically for growth, and add more water as necessary. The Petri dish can be placed on a microscope stage and the culture examined with the $\times 10$ objective lens.
9. When conidia or spores are evident, carefully lift the coverslip off the agar with forceps, and place the coverslip into 1 drop of lactophenol cotton blue on another microscope slide for examination.

PROCEDURE 23

Thermometer calibration

Labeling

1. Create a calibration log sheet.
2. Etch a number on the back of each thermometer using a diamond-tipped marker.

Calibration method

3. Place the reference thermometer and thermometer(s) to be calibrated in an ice bath.
4. When the reference thermometer reads 0°C, take the reading of all thermometer(s) being calibrated, and record the readings on the log sheet.
5. Repeat steps 1 and 2 at all other applicable temperatures, such as 35°C and 56°C.

Calculation of correction factor

6. Correct for the difference in readings between the reference thermometer (reference temperature) and that of each thermometer being calibrated by subtracting the higher reading from the lower reading. If the thermometer being calibrated reads less than the reference thermometer, assign a plus (+) sign to the result of the subtraction step. This value must be added to the thermometer reading to equal the reading that would be taken from the reference thermometer. Conversely, if the reading of the

thermometer being calibrated is greater than the reference thermometer, assign a minus (–) sign to the result. This value must then be subtracted from that thermometer's reading to equal the reference value.

7. Correct for the difference between the reading of the reference thermometer and the "real" temperature using the process just described. Add the correction factor for the reference thermometer to the correction factor calculated in step 1 for each thermometer being calibrated.
8. Determine the correction factor at each temperature for each thermometer, and record it on the log sheet for the thermometer. The log sheet should be kept for the life of the thermometer.
9. Tolerance limits are set by each laboratory but are usually $\pm 1^\circ\text{C}$. Discard all thermometers that exceed the established tolerance limit.

Examples of correction factors are as follows.

"Real" reference	Correction temperature	Temperature factor
0°C	0.1°C	+0.1
37°C	36.9°C	+0.1
56°C	55.9°C	+0.1

Procedure 24

Wright-Giemsa stain, rapid modified

Principle

The Wright-Giemsa stain is available in a modification that requires only 1 to 3 minutes. This neutral dye is a combination of basic thiazine dyes and acid eosin that attach to oppositely charged sites on proteins. The results are metachromatic.

Materials

Wright-Giemsa stain
Absolute methanol
Phosphate buffer, pH 6.0

Application

Wright-Giemsa (modified) is a rapid stain for smears and imprints to stain background materials and cells and a wide variety of microorganisms.

Precautions

Avoid getting reagents in eyes or on skin or clothing; if this occurs, flush with copious quantities of water. Use with adequate ventilation. If stain is discarded into the sink, flush with large volumes of water to prevent azide buildup, which can react with lead and copper plumbing to form highly explosive metal azides.

Procedure

1. Prepare smear or imprint.
2. Fix slide by dipping it into absolute methanol for 15 seconds. After 15 seconds, allow excess to drain.
3. Dip slide in Wright-Giemsa stain for 1 minute. Allow excess to drain.
4. Rinse slide in phosphate buffer for 5 minutes without agitation.
5. Rinse slide briefly with running distilled water.
6. Allow to air-dry. Examine.

Note: The staining intensity may be altered by increasing or decreasing dips in the Wright-Giemsa stain. Reagents and procedures vary slightly by manufacturer. Be sure to follow the protocol on the package insert.

Results

Blood cells stain pink as with the Wright stain. The cytoplasm is basophilic. The chromatin of white blood cells is purple. Bacteria are blue. Parasitic protozoan nuclei are red.

PROCEDURE 25

X and V factor requirement

Purpose

To differentiate *Haemophilus* spp. based on their requirement for X and/or V factors

Principle

A suspension of bacteria to be tested is lawned onto the surface of a minimal medium. Disks or strips impregnated with X, V, and X and V factors are placed on the surface of the medium. After incubation, the pattern of bacterial growth determines which factor(s) the bacteria require.

Specimen

Isolated colonies on chocolate agar

Medium

Trypticase soy broth
Mueller-Hinton or trypticase soy agar plate
X, V, and X and V factors

Procedure

1. Make a suspension of the isolate in trypticase soy broth. The suspension is incubated at 35° C for about 2 hours to exhaust any X and V factors carried over from the plating medium.
2. A swab is used to inoculate the broth onto plated medium devoid of X and V factors; Mueller-Hinton or trypticase soy agars are acceptable.

3. After the plates dry, sterile forceps are used to place a strip or disk containing X factor gently on the plate. A V factor strip or disk is placed parallel to the X factor strip or disk approximately 15 mm away. A greater distance away, a strip or disk containing both X and V factors is placed onto the medium.
4. The plate is incubated at 35° C in 5% to 10% CO₂ for 18 to 24 hours. The plates are then examined for growth around and/or between the strips.

Interpretation

V factor only required: Growth entirely around the V factor disk or strip and the disk or strip containing both X and V factors

X factor only required: Growth entirely around the X factor disk or strip and the disk or strip containing both X and V factors

X and V factors both required: Growth between the X and V disks or strips and growth around the disk or strip containing both X and V factors

Controls

V factor only required: *Haemophilus parainfluenzae*

Both X and V factors required: *Haemophilus influenzae*

Glossary

5' nuclease assay Real-time polymerase chain reaction (PCR) detection technique; also called the *Taqman assay*. This assay uses a probe labeled on the 5' end with a fluorophore and on the 3' end with a quencher. The probe binds to target DNA and is dissociated by the action of DNA polymerase when primer extension occurs. The dissociation of the probe results in fluorescence because the fluorophore and quencher are removed from close proximity.

A

accuracy Degree of conformity of a measurement to a standard or a true value.

achlorhydria Absence of hydrochloric acid from the gastric juice.

acid-fast See **acid-fastness**.

acid-fast bacteria Microorganisms that are resistant to the removal of carbolfuchsin stain with acidified alcohol are designated as acid-fast bacteria. Mycobacteria and related species with waxes and phospholipids in their cell walls share this feature.

acid fastness Ability of bacteria, such as the *Mycobacterium* spp., to retain dye when treated with mineral acid or an acid-alcohol solution.

acquired immune system See **adaptive immunity**.

acquired immunodeficiency syndrome (AIDS) The most severe clinical manifestation of the disease spectrum caused by human immunodeficiency virus (HIV) infection.

acquired resistance See **adaptive immunity**.

actinomycosis (pl. actinomycoses) Chronic, granulomatous, infectious disease characterized by the development of sinus tracts and fistulae that erupt to the surface and drain pus containing sulfur granules. It is caused by *Actinomyces israelii* and related anaerobic organisms.

actinomycotic mycetoma Mycetoma caused by bacteria belonging to the group actinomycetes.

acute glomerulonephritis Poststreptococcal disease that occurs after a cutaneous or pharyngeal infection that results from antigen-antibody complexes deposited in the glomeruli.

acute otitis media. See **otitis media**.

acute phase Early stage of a disease preceding the adaptive phase of the immune response.

acute urethral syndrome Condition in which patients experience dysuria and frequency with bacterial urine colony counts fewer than 10^5 organisms/mL of urine.

adaptive immune response See **adaptive immunity**.

adaptive immunity Immune response elicited by a specific stimulus from a foreign molecule that causes immunogen recognition by B, T-helper, or cytotoxic T cells and results in the proliferation and differentiation of the stimulated cells into effector cells and memory cells; an immunity resulting

from a previous encounter of the host and an immunogenic stimulus.

adenylate cyclase toxin Virulence factor of *Bordetella* spp. that inhibits host epithelial and immune effector cells by inducing supraphysiologic concentrations of cyclic adenosine monophosphate.

adhesin Thin, filamentous, protein structures, including proteinaceous capsular antigens (fimbrial antigens), that mediate the adhesion of bacteria to surfaces and play a role in pathogenesis. They have a high affinity for various epithelial cells.

aerobe Microorganism that lives and grows in the presence of oxygen or requires oxygen.

aerobic respiration Process of cellular respiration utilizing oxygen to produce energy.

aerotolerance test Test used to determine whether an isolate is a strict anaerobe or a facultative anaerobe.

aerotolerant anaerobe Microorganism that grows best in the absence of oxygen but can tolerate low concentrations of oxygen.

agar dilution minimal inhibitory concentration (MIC) Assay in which a specific concentration of antimicrobial agent is incorporated into an agar medium contained in a Petri plate to determine the lowest concentration of the assayed antimicrobial agent that inhibits visible growth of the bacterium being tested. As many as 36 bacterial isolates from individual patients and quality control strains are tested on a series of agar dilution plates, each containing a different concentration of antimicrobial agent.

agarose gel electrophoresis Method used to separate nucleic acid molecules. Agarose is made from seaweed and acts as a molecular sieve. Nucleic acids migrate through the agarose gel when an electrical current is applied. Nucleic acids are naturally negatively charged and will migrate to a positive pole separating the molecules based on mass and charge.

amastigote Life-cycle stage found in humans that is characteristic of blood and tissue flagellates. It is a small, oval, intracellular body with a prominent nucleus and small kinetoplast.

aminoglycoside An antibiotic that has a six-membered ring with amino group substituents, aminocyclitol. The term *aminoglycoside* is so named because of the glycosidic bonds between the aminocyclitol and two or more amino-containing or non-amino-containing sugars.

δ -aminolevulinic acid (ALA) Substrate used in biochemical testing of *Haemophilus* spp. to determine X factor (hemin) requirement.

amorphous debris Debris without form or shape that is made up of necrotic tissue or cells, protein fluids, or mucus.

amplicon Amplified DNA that results from several cycles of the polymerase chain reaction (PCR); also known as a *PCR product*.

- anaerobe** Organism that does not require oxygen for life and reproduction.
- anaerobic chamber** Incubation system that provides an oxygen-free environment for inoculating media and incubating cultures.
- anaerobic transport system** Systems designed to maintain the viability of anaerobic bacteria from the time of collection to processing of the specimen. The vials are gassed out with oxygen-free carbon dioxide or nitrogen and contain an oxygen tension indicator.
- analytic activity** Process of analyzing a sample.
- analytic sensitivity** Ability of a test to detect a particular analyte or a small change in its concentration.
- analytic specificity** Ability of a test to detect substances other than the analyte of interest.
- anamnestic immune response** Stronger, quicker humoral or cell-mediated response on subsequent exposure to an immunogen.
- anamnestic response** See **anamnestic immune response**.
- anamorph** Form of a fungus that reproduces asexually.
- anneal** Pairing, using hydrogen bonding, of complementary RNA and DNA sequences to form a double-stranded molecule; describes the binding of a short probe or primer.
- annealing temperature (Ta)** The optimal temperature at which two complementary strands of nucleic acid form a double-stranded molecule.
- antagonism** Occurs when the antimicrobial activity of a combination of antimicrobial agents is less than the activity of the individual agents alone.
- anthrax** Disease of livestock with which humans are accidentally infected. In humans, it can take four clinical forms: cutaneous, gastrointestinal, injectional, and inhalational (pulmonary anthrax); an infection associated with *Bacillus anthracis*.
- antibiogram** Compilation of selected microorganisms and the percentage susceptibility to selected antimicrobial agents.
- antibiotic** Substance produced by a microorganism used to prevent or treat infection caused by bacteria and other pathogenic microorganisms.
- antibiotic stewardship** The effort to measure and improve how antimicrobial agents are prescribed by primary care providers and used by patients.
- antibody** Protein, which in the monomer form has two heavy and two light chains, consisting of a hypervariable region capable of recognizing a particular binding site on another molecule; an immunoglobulin molecule characterized by a specific amino acid sequence produced by the host as a result of a specific immunogenic stimulation.
- antibody titer** Reciprocal of the highest dilution of a clinical sample that can be detected in a reaction with the corresponding antigen.
- anticodon** Triplet of bases on the tRNA that binds the triplet of bases on mRNA. It identifies which amino acid will be in a specific location in the protein.
- antigen** A molecule that exhibits reactivity with an immunologic effector, such as an antibody or T-cell receptor.
- antigenic drift** Phenomenon of slight antigenic change seen in influenza viruses over time as a result of minor mutations in the ssRNA genome.
- antigenic shift** Phenomenon whereby an often unexpected change occurs in influenza virus strains. This antigenic change is often so drastic that it triggers pandemics.
- antigenic variation** Systematic change in surface antigens while organisms such as *Borrelia recurrentis* are in the host during the course of a single infection.
- antimicrobial agent** Substance used to prevent or treat infection caused by bacteria and other pathogenic microorganisms.
- antimicrobial assay** Method to measure the amount of antimicrobial agent in serum or body fluid.
- antimicrobial pressure** Antimicrobial use induces selection pressure, allowing only the fittest and least susceptible bacterial populations to thrive and thereby displace susceptible populations; also referred to as *antimicrobial selection pressure*.
- antimicrobial removal device (ARD)** Resin that nonspecifically absorbs any antimicrobial agent present in the patient's blood.
- antiseptics** Destruction of microorganisms to prevent infection.
- antiseptic** Substance that inhibits, destroys, or reduces the bacterial load of living tissues. No sporicidal activity is implied; used specifically for substances applied to living tissue.
- antiseptic drug** Considered to be a representative germicide, except in the case of a drug purporting to be, or represented as, an antiseptic for inhibitory use as a wet dressing, ointment, dusting powder, or other use that involves prolonged contact with the body.
- appliqué form** Parasite at the edge of a red blood cell.
- arbovirus** Virus transmitted between vertebrate hosts by arthropods.
- archaea** Group of living microorganisms that exist in extreme conditions, such as in the absence of oxygen; in bodies of highly concentrated salt water; in hot, acidic waters of sulfur springs; and at temperatures near 80° C and pH levels as low as 2. They are classified as prokaryotes but are distinct from bacteria.
- arthroconidium** Asexual spore formed by the breaking of a hypha at the point of septation. Arthroconidia can be adjacent or separated by a disjunct cell.
- asaccharolytic** Microorganism that is unable to metabolize carbohydrates in the presence or absence of oxygen and that must rely on other carbon sources for energy.
- ascospore** Sexual spore produced by fusion of a male nucleus into a female cell in an ascus.
- ascus** Saclike structure usually containing two to eight ascospores.
- aseptic meningitis** Syndrome characterized by signs and symptoms of meningeal inflammation with the presence of inflammatory cells in the cerebrospinal fluid without bacteria or fungi recovered from cultures; often associated with meningitis caused by viruses.
- asexual reproduction** Reproduction by methods such as fission, in which the nucleus and cytoplasm are split to form two new, separate organisms.
- Asiatic cholera** See **cholera**.
- aspiration pneumonia** Pulmonary inflammation resulting from the abnormal entry of fluid, particulate substances, or endogenous secretions into the lower airways.

asymptomatic bacteriuria (ASB) The presence of bacteria in the urine without any symptoms of a urinary tract infection.

atypical pneumonia See **primary atypical pneumonia**.

auramine/auramine-rhodamine fluorochrome

stains Fluorochrome stains (auramine or auramine-rhodamine) are used to visualize acid-fast bacteria using a fluorescence microscope. Acid-fast bacteria appear yellow or orange.

autotroph Organism that produces organic compounds from carbon dioxide as a carbon source, using light or inorganic chemical compounds as a source of energy.

avibactam A non- β -lactam β -lactamase inhibitor used in combination with ceftazidime.

avidity Strength of binding between an antibody molecule and an antigen with multiple epitopes.

axostyle An axial rod present in several intestinal flagellates providing support.

B

Babès-Ernst granules Metachromatic granules of *Corynebacterium diphtheriae* that stain more intensely than other parts of the bacterial cell.

bacillary dysentery Gastrointestinal disease caused by bacterial infection. Symptoms include severe diarrhea, fever, stomach pain, nausea, and vomiting.

bacteremia Presence of viable bacteria in the blood, as evidenced by their recovery in blood cultures.

bacteria Also referred to as *eubacteria*; single-celled procaryote, microorganisms that lack a true cell nucleus and multiply by binary fission.

bacterial interference Potential pathogens inhibited by the nonpathogenic resident microbiota.

bacterial vaginosis (BV) Syndrome characterized by vaginal symptoms that include perivaginal irritation, vaginal odor described as fishy, and mild to moderate discharge. The condition is regarded as being polymicrobial.

bactericidal Antimicrobial that kills a microorganism.

bactericidal effect Killing effect or amount of antimicrobial agent required to kill a population of bacteria.

bacteriocin Proteins produced by some bacteria that inhibit the growth of other strains of the same organism or related species. Genes for bacteriocins may reside on plasmids.

bacteriophage Virus that infects bacteria.

bacteriostatic Antimicrobial that inhibits bacterial growth while present but does not kill the bacteria.

bacteriuria Presence of bacteria in the urine.

balanitis Inflammation of the glans (head) of the penis.

bamboo rods Term that describes the microscopic appearance of *Bacillus anthracis* in a Gram-stained smear, referring to the cells' arrangement and the unstained central spore.

baseline data Surveillance data that represent the normal endemic level of infections in a health care setting; used to gauge when an outbreak occurs.

Bayes theorem Formulas for calculating positive and negative predictive values are commonly referred to as *Bayes theorem*, published posthumously in 1763.

benchmarking Reference point obtained by using an industry's or profession's best practices to imitate and improve processes.

bias Mean difference of test results from an accepted reference method by systemic errors.

bile solubility Test that determines the ability of bacterial cells to lyse in the presence of bile salts; it is used to differentiate *Streptococcus pneumoniae* (bile-soluble) from other α -hemolytic streptococci (bile-insoluble).

biocrime Refers to a situation in which a biological agent is used to kill or make ill a single individual or small group of individuals.

biofilm Community of microorganisms attached to a solid surface.

biofouling Undesirable accumulation of microorganisms, plants, algae, and/or animals on wetted structures. For example, biofilms can form in pipes carrying drinking water, making the water unsafe to drink.

biological agent Any microorganism (including, but not limited to, bacteria, fungi, rickettsiae, or protozoa), or infectious substance (e.g., virus), or any naturally occurring, bioengineered, or synthesized component of any such microorganism or infectious substance, capable of causing the following: death, disease, or other biological malfunction in a human, animal, plant, or other living organism; deterioration of food, water, equipment, supplies, or material of any type; or deleterious alteration of the environment.

biological risk assessment Assessment of biological hazards.

biological safety cabinet (BSC) A station for the safe handling of aerosols and particulates; provides laboratory personnel protection.

biological warfare Deliberate use of bacteria, viruses, fungi, or toxins to injure people, animals, or crops to gain a military advantage or for political gain.

biorisk The risk associated with biological materials and/or infectious agents.

biorisk management The effective management of risks posed by working with infectious agents and toxins in laboratories.

biosafety The use of specific practices, safety equipment, and specially designed buildings to ensure that workers, the community, and the environment are protected from accidental exposure or unintentional release of infectious agents, toxins, and other biological hazards.

biosafety cabinet See **biological safety cabinet**.

biosafety level Maintenance of safe conditions in the laboratory environment to prevent harm to workers, nonlaboratory organisms, or the environment. The Centers for Disease Control and Prevention has established guidelines for four biosafety levels.

biosecurity Procedures intended to protect humans or animals against disease or harmful biological agents.

biosurveillance Systematic observation and data gathering to detect and counter biological threats to human or animal health, in order to achieve early warning and identification of such health threats, and general situational awareness of disease activity.

bioterrorism Intentional use of biological agents (bacteria, viruses, or toxins) to cause illness or death as an act of terrorism.

biothreat The threat posed by a harmful biological agent.

biotin-streptavidin system Immunologic assay based on the interaction of biotin with streptavidin. Antibody is linked to biotin. If an antigen specific to the antibody is present in a clinical specimen, it will bind to the antibody. After a wash step, streptavidin linked to a label (e.g., enzyme or fluorochrome) is added. Biotin and streptavidin will bind and the signal is measured.

bipolar staining Refers to the distinctive safety pin appearance that results from staining with a polychromatic stain such as Wayson or Wright-Giemsa stain.

black death Another name for plague, a disease caused by *Yersinia pestis*.

blackwater fever Syndrome associated with *Plasmodium falciparum* infection characterized by reddish to black urine resulting from hemoglobinuria.

blastoconidium Conidium formed by budding yeast along the hypha or pseudohypha or from a yeast cell.

blepharitis Inflammation of the eyelids.

bloodborne pathogen Pathogenic microorganism that is present in human blood and can cause disease in humans. These pathogens include, but are not limited to, hepatitis B virus and human immunodeficiency virus.

borderline oxacillin-resistant isolates Subtle type of oxacillin resistance in *Staphylococcus aureus* that lack the *mecA* gene and have oxacillin minimal inhibitory concentrations (MICs) right above (or zones of inhibition right below) the breakpoint for susceptibility.

borderline oxacillin-resistant *Staphylococcus aureus* (BORSA) See **borderline oxacillin-resistant isolates**.

Bordet-Gengou potato infusion agar Medium supplemented with glycerol, peptones, and horse or sheep blood for isolation of *Bordetella* spp.

botulinum toxin Neurotoxin primarily produced by *Clostridium botulinum*.

botulism Serious form of food poisoning caused by the ingestion of preformed botulinum toxin produced by *Clostridium botulinum*.

bradyzoite *Toxoplasma gondii* life-cycle stage that forms within a cystlike structure. The organisms multiply slowly but may be transformed into tachyzoites when the host's immune system is impaired.

brain abscess Swollen area in the brain tissue containing pus caused by inflammation and collection of infected material coming from a local infectious source (e.g., ear infection, infection of the paranasal sinuses, infection of the mastoid air cells of the temporal bone, epidural abscess) or remote infectious source (e.g., lung, heart, kidney).

branched DNA (bDNA) assay Technique that amplifies a signal after probes have annealed to target nucleic acid; a capture probe attached to a solid support anneals to target nucleic acid. Target probes also anneal to the nucleic acid and to preamplifier probes. Amplifier probes then bind to the preamplifier probes, resulting in the formation of branched DNA (bDNA) structures. Label probes then bind to the bDNA structures, resulting in massive signal amplification.

breakpoint Minimal inhibitory concentration or zone diameter value used to indicate susceptible, intermediate, or resistant for an antimicrobial agent, as defined by the interpretive criteria used in Clinical and Laboratory Standards Institute standards.

breakpoint panel Variation of the standard broth microdilution minimal inhibitory concentration panel is the breakpoint panel, in which only one or a few concentrations (around the cut off between sensitive and resistant) of each antimicrobial agent are tested on a single panel.

Brill-Zinsser disease Reactivation of *Rickettsia prowazekii* in patients who have had epidemic typhus. The reactivation disease is normally milder than epidemic typhus; also called *recrudescence typhus*.

brittle Adjective used in defining colony consistency; splinters.

bronchiolitis An infectious disease usually of infants and young children usually caused by respiratory viruses, characterized by inflammation of the bronchioles and clinically expressed as a febrile upper respiratory tract infection, with concurrent signs of lower respiratory tract airway obstruction.

bronchitis Illness characterized by inflammation of the bronchi; clinically expressed as cough, usually with sputum production, and evidence of concurrent upper airway infection.

bronchoalveolar lavage Procedure in which saline or some other physiologic fluid is instilled into the alveoli and recovered for the purpose of culture or cytology examination.

broth macrodilution minimal inhibitory concentration (MIC) Broth dilution MIC tests performed in test tubes are referred to as *broth macrodilution MIC* or *tube dilution MIC* tests. Generally, a twofold serial dilution series, each containing 1 to 2 mL of antimicrobial agent, is prepared.

broth media Liquid medium used as a supplement to agar plates to detect small numbers of most aerobes, anaerobes, and microaerophiles.

bubo (pl. buboes) Inflammation of a lymph node, characterized by swelling and ulceration, resulting from infection, especially in the area of the armpit or groin, that is characteristic of certain infections such as bubonic plague; inflamed, tender swelling of a lymph node.

bubonic plague Most common form of plague, which usually results from the bite of a flea infested with *Yersinia pestis*. A common result is the formation of a bubo.

buffered charcoal yeast extract (BCYE) Recommended medium for isolation of *Legionella* spp. It should be supplemented with α -ketoglutarate.

bullae (pl. bullae) Blister larger than 5 mm (about ¼ inch) in diameter with thin walls that is full of fluid.

bullous impetigo Form of impetigo in which the skin lesions are bullae instead of vesicles. The crusts are thin and greenish yellow. Exfoliative toxin has been implicated in bullous impetigo. See **impetigo**.

Buruli ulcer Infectious disease caused by *Mycobacterium ulcerans* characterized by painless swelling that later develops into a lesion.

butyrous Adjective used in defining colony consistency; creamy.

C

CAMP test CAMP stands for Christie, Atkins, and Munch-Peterson, a test used for the presumptive identification of group B streptococci (*Streptococcus agalactiae*). A positive result is determined by enhanced, arrowhead, β -hemolysis from the interaction of CAMP factor from group B

- Streptococcus* and the β -lysine from certain strains of *Staphylococcus aureus*.
- canaliculitis** Inflammation of the canaliculus, thin channel in bone.
- capnophile** Microorganism that grows best in the presence of carbon dioxide.
- capnophilic** Term used to describe microorganisms that require an increased concentration of CO₂, usually between 5% and 10%.
- capsid** Protein covering a virus.
- capsule** Structure in some prokaryotic cells located outside the cell wall of bacteria. It is usually made up of polysaccharides but could be composed of other materials; used by microorganisms as a protective structure against phagocytosis and physical and chemical effects of the environment.
- carbapenemase-producing Enterobacterales (CPE)** Member of the order Enterobacterales that produces a carbapenemase, a β -lactamase able to hydrolyze several antibiotics, including penicillins, cephalosporins, monobactams, and carbapenems.
- carbuncle** Cluster of furuncles caused by the subcutaneous spread of a staphylococcal infection.
- carrier** Individual or animal that harbors a potentially pathogenic organism or infectious agent without the host showing signs of the disease, but that serves as a source of infection to susceptible individuals.
- carrier state** Condition in which an individual or animal harbors a potentially pathogenic organism or infectious agent without the host showing signs of the disease, but that serves as a source of infection to susceptible individuals.
- Cary-Blair transport media** Semi-solid medium used for the maintenance of various pathogens, including enteric bacteria such as *Salmonella*, *Shigella*, and *Campylobacter* spp. in stool specimens.
- case definition** Description establishing parameters that define a case in an outbreak investigation.
- catalase** Breaks down hydrogen peroxide to water and oxygen. Useful for distinguishing staphylococci (positive) from streptococci (negative).
- catarrhal phase** Initial phase of pertussis. Symptoms are nonspecific and include sneezing, mild cough, runny nose, and sometimes conjunctivitis.
- category A agents** Bacteria, viruses, and toxins that, if used as bioterror agents, would cause significant public health disruption.
- catheter-associated urinary tract infection (CAUTI)** Urinary tract infection linked to the use of a urinary catheter.
- catheter-related bloodstream infection (CRBSI)** Bloodstream infection related to the presence of an intravascular device in a major vessel, generally ending at or near the heart.
- cell culture** Cells removed from an organism and grown in a complex medium for several purposes, including growth of viruses.
- cell wall-deficient** Refers to gram-positive or gram-negative bacteria lacking a cell wall; also called *L forms*. Exposure to antimicrobial agents that inhibit cell wall synthesis (e.g., penicillin) can lead to this condition. The mycoplasma inherently lack the ability to produce a cell wall; therefore when they were first discovered, they were referred to as *cell wall-deficient*.
- cell-mediated immune response** Adaptive immune response that involves activation of macrophages and natural killer cells; production and release of antigen-specific, cytotoxic T lymphocytes; and release of various cytokines in response to an immunogenic stimulus. It does not involve antibodies.
- cellulitis** Serious, sometimes life-threatening, skin infection that involves deep tissues; can be accompanied by bacteremia or sepsis.
- Centers for Disease Control and Prevention (CDC)** A federal agency established for the protection of the health and safety of people, at home and abroad, that provides information to enhance health decisions and health promotion.
- central line-associated bloodstream infection (CLABSI)** One of multiple acute-care, hospital-acquired infections; occurs as a result of instrumentation, increased use of antimicrobial agents, breaks in aseptic technique, and lack of hand hygiene.
- central nervous system (CNS)** The largest part of the nervous system; made up of the brain and the spinal cord.
- cercaria** Tailed stage in the life cycle of flukes that is produced from miracidia that develop in snail tissue. This stage is released into the water.
- cerebrospinal fluid (CSF)** Clear fluid formed by the choroid plexus or ventricles that fills the subarachnoid space in the brain and serves as a cushion for the cortex.
- cervicitis** Inflammation of the tissues surrounding the cervix; can be caused by infection by a variety of agents, such as *Chlamydia trachomatis* and *Neisseria gonorrhoeae*.
- cervicofacial actinomycosis** Infectious disease caused by the anaerobic *Actinomyces*, which can occur in the mouth, lungs, and digestive tract. Abscesses may penetrate the surrounding bone and muscle to the skin, where they break open and leak large amounts of pus. When it occurs in the face or neck, it is termed *cervicofacial*.
- chancre** See *syphilitic chancre*.
- chancroid** Sexually transmitted disease (infection) caused by *Haemophilus ducreyi*.
- chemiluminescent immunoassay (CLIA)** Type of labeled assay when a chemical reaction emits light.
- chemotactic agent** Protein that is able to direct the migration of a specific cell.
- chemotaxis** Movement of cells in response to a chemical stimulant.
- chlamydia** The most commonly reported infectious disease in the United States. Chlamydia is caused by the obligate intracellular bacterium *Chlamydia trachomatis*, which has a biphasic developmental cycle.
- chlamydiosis** Infection caused by *Chlamydia* spp.
- cholera** Acute, infectious, diarrheal illness caused by *Vibrio cholerae*, which may occur in epidemic proportions.
- cholera toxin** Powerful enterotoxin produced by *Vibrio cholerae*; also referred to as *cholera toxin*.
- cholera toxin** See *cholera toxin*.
- chromatoidal bar** RNA that has been condensed into a barlike structure within the cyst of some protozoan organisms.
- chromoblastomycosis** See *chromomycosis*.
- chromogenic substrate** Molecule that is initially colorless; when cleaved by a specific enzyme, it becomes a colored compound.

chromomycosis Chronic fungal infection of the skin and subcutaneous tissues, also called *chromoblastomycosis*. The most commonly associated fungi are *Fonsecaea pedrosoi*, *Phialophora verrucosa*, *Cladophialophora carrionii*, and *Fonsecaea compacta*.

chromosomally mediated resistant *Neisseria gonorrhoeae* (CMRNG) Type of penicillin resistance in *N. gonorrhoeae* attributable to genes located on the chromosome that code for an alteration in penicillin-binding proteins.

-cidal Suffix used to indicate that a substance destroys microorganisms (e.g., bactericidal, virucidal).

ciguatera Form of food poisoning caused by ciguatera toxin produced by dinoflagellates; passed up the food chain; ingested in snapper, sea bass, or grouper.

citrate test Bacteriologic test to determine an organism's ability to use citrate as a sole carbon source.

Clark and Lub's medium Classic bacteriologic medium used for the methyl red, Voges-Proskauer test.

clavulanic acid A β -lactamase inhibitor often used with amoxicillin.

clean-catch midstream urine specimen A urine sample collected using a technique that reduces contaminant skin biota; the patient cleanses the external genitalia and begins voiding urine, collecting the sample midstream.

Clinical and Laboratory Standards Institute (CLSI) International, interdisciplinary, nonprofit, standards-developing, educational organization that promotes the development and use of voluntary consensus standards and guidelines in the health care community.

Clinical Laboratory Improvement Amendments (CLIA) Law first released in 1988, with subsequent amendments, establishing quality standards for all laboratory testing to ensure accuracy, reliability, and timeliness of patients' test results.

clinical (diagnostic) sensitivity Proportion of positive test results obtained when a test is applied to patients known to have a disease.

clinical (diagnostic) specificity The proportion of negative results obtained when a test is applied to patients known to be free from a disease.

***Clostridioides difficile*-associated disease** Disease characterized by damage to the lining of the colon; caused by *Clostridioides difficile*; also referred to as pseudomembranous colitis.

clumping factor Cell-bound coagulase that is able to agglutinate cells in plasma; may be used to screen for *Staphylococcus aureus*.

coagglutination Particulate agglutination assay using *Staphylococcus aureus* to bind the Fc portion of antibodies.

coagulase Clotting enzyme (staphylocoagulase) useful in differentiating coagulase-positive staphylococci, such as *Staphylococcus aureus*, from coagulase-negative staphylococci.

coagulase-negative staphylococci (CoNS) Staphylococci that lack the enzyme coagulase.

codon Gene sequence inscribed in DNA and RNA composed of trinucleotide units.

cold-agglutinating antibody Antibody that agglutinates antigens at 4° C; if present, suggestive of infection caused by *Mycoplasma pneumoniae*.

cold enrichment Method of incubating broth cultures at 4° C for several days to select for bacteria, such as *Listeria* and *Yersinia* spp., that grow well at this temperature.

College of American Pathologists (CAP) The principal organization of board-certified pathologists that serves and represents the interest of patients, pathologists, and the public by fostering excellence in the practice of pathology and laboratory medicine.

colonization Formation of a population of microorganisms in the host that does not cause disease.

colony-forming unit (CFU) Number of microbes that grow from a measured inoculation; expressed as CFU/mL. Bacteria are easily seen in direct smears at concentrations of 10×5 CFU/mL following cyto centrifugation.

colony morphology Colony characteristics and form of microorganisms grown on solid media.

commensal Refers to an organism that lives in a relationship in which one organism (commensal) derives food or other benefits from another organism (host) without hurting or helping the host.

commensalism Relationship between different species in which one (commensal) benefits from the other (host) without causing harm. The host species does not benefit from the relationship or organism.

communal living Community living program; might include prisons and behavioral health facilities. In these facilities, infections might be found that are spread by contact (illicit tattooing) or by intimate contact with blood and body fluids.

community-acquired bacteremia Bacteremia that occurs in individuals living in the general community.

community-acquired infection Infection that starts in the community and is not acquired in a health care setting.

community-acquired pneumonia (CAP) A pneumonia acquired from a community source as opposed to in a health care facility.

community-associated, methicillin-resistant *Staphylococcus aureus* (CA-MRSA) Infections caused by MRSA that are acquired in the community. CA-MRSA infections and outbreaks have been reported among athletes, correctional facility inmates, military recruits in close-contact environments, pediatric patients, and tattoo recipients. See also **methicillin-resistant *Staphylococcus aureus* (MRSA)**.

competency Ability to apply relevant knowledge, skills, and abilities to successfully perform all assigned duties.

competent As in an immunocompetent patient, refers to a state of well-being in which the immune system is functioning properly and is able to protect the individual from infectious diseases. As in genetics, a cell, such as a bacterium, able to take in DNA fragments from the environment.

competitive immunoassay A labeled antibody or antigen competes with an unlabeled antibody or antigen from a patient. Signal is inversely proportional to the analyte concentration.

complement system Series of plasma proteins that functions as an enzyme or as binding protein; plays an essential role in host defense against infectious agents and in the inflammatory process.

complement deficiency Lack of any one or more of the proteins that make up the biochemical cascade of the complement system.

complement fixation (CF) Activation of complement proteins. Also an immunoassay method using complement proteins as a means to detect immunocomplexes.

condyloma acuminatum (pl. acuminata) Anogenital warts caused by human papillomavirus.

condylomata lata Flat, mucoid, fleshy, wartlike growths that often occur in the perianal region but can occur in other moist regions of the body; papules of secondary syphilis.

congenital infection Refers to being acquired in utero when the organism infecting a woman crosses the placenta to infect the fetus.

conidium Asexual fungal reproductive structure usually formed at the side of hyphae. It is not contained in a saclike structure; small and usually single-celled conidia are called *microconidia*, and larger multicelled conidia are called *macroconidia*.

conjugate Substance formed by combining two different molecules, specifically in immunologic assays, adding an enzyme or fluorochrome to an antibody or antigen.

conjugation Transfer of genetic material between bacteria through cell-to-cell contact.

conjunctivitis Inflammation of the conjunctiva (the mucous membrane that covers the front of the eye and lines the inside of the eyelids).

consistency Degree of a feature such as density, firmness, viscosity, and texture.

continuing education Educational learning activities that adults pursue postsecondary or after any formal education; may include seminars and one-time online courses and other forms of training.

continuous bacteremia Bacteremia (see earlier) that occurs when organisms are coming from an intravascular source and are consistently present in the bloodstream.

continuous cell culture Culture capable of a virtually unlimited number of passages, sometimes referred to as an *immortal cell culture*.

continuous quality improvement (CQI) Progressive incremental improvement of processes, safety, and patient care.

onalescent phase In pertussis, the third and final phase, generally beginning within 4 weeks of onset of infection. There is a decrease in the frequency and severity of the coughing spells; complete recovery occurs in weeks to months.

creamy See *butyrous*.

creeping eruption Rash caused by the movement of hookworm larvae beneath the surface of the skin.

cross-functional teams Teams composed of members from different departments.

cumulative antibiogram Report generated by analysis of individual susceptibility results on isolates from a particular institution in a defined period; represents the percentage of isolates of a given species susceptible to the antimicrobial agents commonly tested against the species.

Curschmann spirals Condensed bronchial secretions that take on the shape and size of bronchial passageways, particularly if there is constriction or obstruction.

customer concepts View or perception each laboratory customer holds in regard to quality and his or her own expectations.

cycling probe technology Technique that amplifies a signal after a DNA-RNA-DNA chimeric probe is incubated with a target nucleic acid. The probe has a 5' fluorophore and a 3' quenching molecule; the result is no fluorescence until the probe anneals to the target nucleic acid. RNase H digests the RNA in the probe after annealing has occurred, resulting in fluorophore release from the quencher. This results in an increase in fluorescent signal. A new probe molecule will then anneal to the same target nucleic acid, and the process repeats for more fluorescence.

cyst Infective form of a protozoan; characterized by the formation of a thick protective wall that is resistant to environmental factors.

cysticercus Larval stage of *Taenia* spp.; fluid-filled sac that contains the scolex of the tapeworm.

cystine-tellurite blood agar (CTBA) Selective and differential medium for the recovery of *Corynebacterium diphtheriae* and related organisms.

cystitis Inflammation of the urinary bladder.

cytocentrifugation Mechanical process in which centrifugal force is used in an instrument to deposit cells on a glass slide for staining and viewing.

cytolytic toxins Exotoxins that can affect erythrocytes, leukocytes, macrophages, and platelets.

cytopathic effect (CPE) Visible changes in cells resulting from toxins or virus infection.

cytostome A mouthlike opening present in certain protozoa.

D

D-zone test Test used to detect inducible clindamycin resistance in staphylococci and β streptococci. An erythromycin disk is placed next to a clindamycin disk on a standard disk diffusion plate; flattening of the clindamycin growth inhibition zone between the two disks indicates inducible clindamycin resistance.

dacryoadenitis Infection of the lacrimal gland.

dacryocystitis Infection of the lacrimal sac.

darting motility Distinct type of rapid motility, characteristic of *Campylobacter* spp., observed under a wet preparation; results from their long polar flagellum.

data mining Computer-based search of data to indicate areas of potential concern for an infection control practitioner; implies in-depth correlation of computer data.

deaminase Enzyme that removes amine groups (NH_2) from amino acids.

decarboxylase Enzyme capable of removing a carboxy group (CO_2) from an amino acid.

decolonization Process to reduce the population of certain bacteria on select patient populations, such as patients in intensive care units.

definitive host Individual in which a parasite has its adult and/or sexual reproductive stage.

denaturation Dissociation of double-stranded nucleic acid molecules into single strands. Denaturation is usually accomplished in molecular biology techniques with high heat (-95°C) so primers or probes may then anneal to target nucleic acid sequences.

dendrogram Branching, treelike diagram frequently used to show the interrelationships among a group of organisms.

density Degree of opacity of a substance or medium that transmits light.

deoxynucleotide triphosphate (dNTP) Individual nucleic acid base used by enzymes such as DNA polymerase to synthesize new nucleic acid strands. Adenine (dATP), cytosine (dCTP), guanine (dGTP), and thymidine (dTTP) are used by DNA polymerase to synthesize new DNA strands.

dermatophyte Fungus able to use keratin and infect the skin, hair, and nails of humans; belongs to the genera *Epidermophyton*, *Microsporum*, and *Trichophyton*.

dermatophytosis Infection caused by a dermatophyte.

detection limit Analytic sensitivity is usually defined at the 0.95 confidence level (± 2 standard deviations); may be referred to as the detection limit. In microbiology, the detection limit may be correlated to the number of colonies in the culture or to the lowest quantity of antigen or antibody a test can detect.

diapedesis Passage of inflammatory cells and other formed elements in the blood through the endothelial walls of the blood vessel.

differential media Media that allow grouping of microbes based on different characteristics demonstrated on the medium (i.e., colony morphology).

differential stain The Gram stain colorizes cells differently so each component can be recognized (gram-positive cell wall, gram-negative cell wall).

diffusely adherent *Escherichia coli* (DAEC) Enteropathogenic and uropathogenic *E. coli* strains defined by their attachment to HEp-2 cells.

dimorphic fungi Fungi that exist as a yeast, spherule, or mold, depending on growth conditions.

diphtheria Disease caused by *Corynebacterium diphtheriae*.

diphtheria toxin Potent toxin produced by *Corynebacterium diphtheriae* that causes tissue necrosis, exudate formation, and systemic effects involving the heart, kidneys, and nervous system.

diploid Containing two copies of each chromosome. Diploid is the normal genetic makeup for eukaryotic cells.

diploid cell culture Cells used for the growth of viruses that contain the normal number of chromosomes.

direct agglutination test Agglutination assay in which the antigen naturally occurs on a cell.

direct fluorescent antibody (DFA) test Assay using a fluorochrome-labeled primary antibody to detect an antigen in a clinical specimen or culture isolate.

direct microscopic examination Examination of the specimen under a microscope, with or without staining.

direct sandwich immunoassay Assay in which an antigen is captured by an antibody affixed to a solid phase. A second labeled antibody is added that is able to bind to the antigen.

disinfectant Substance designed to be used on inanimate objects to kill or destroy disease-producing microorganisms, including spores in some cases.

disinfection Reduction in the amount of microbes that may cause disease from an environment.

disseminated intravascular coagulation (DIC) Pathologic activation of blood-clotting mechanisms that occurs in response to a variety of disease states, which leads to the formation of small blood clots inside the blood vessels throughout the body.

dissemination Spread to other sites.

DNA microarray Technique used to assay the entire expression of genes in cells; also can be used to identify organisms from samples, mutations, and new genes, and for other purposes. Microscopic spots of single-stranded DNA are placed on a solid support in an array, and unknown samples are fluorescently labeled and hybridized to the DNA on the array. A scanner is used to identify hybrids and indicate positive samples or high levels of gene expression.

DNA polymerase Enzyme that synthesizes new strands of DNA. DNA polymerase uses deoxynucleoside triphosphates and primers to synthesize the new strands. The most common DNA polymerase in use in molecular diagnostics methods is *Taq* DNA polymerase, a thermostable enzyme that can withstand the denaturation temperatures used in polymerase chain reaction and other methods.

DNA replication Copying of a double-stranded DNA strand in a cell before cell division.

DNA transcription Process through which a DNA sequence is enzymatically copied by an RNA polymerase to produce complementary RNA.

DNase Enzyme capable of hydrolyzing double-stranded DNA.

Donovan bodies Characteristic intracellular organisms found in Giemsa or Wright stain of macrophages that can confirm the diagnosis of donovanosis. Donovan bodies measure 0.5 to 0.7 mm $\times$ 1 to 1.5 mm in diameter and may or may not be capsulated. See also **granuloma inguinale**.

double immunodiffusion An immunologic assay performed in agarose. Antigen is placed in a well near a well containing an antibody. The reactants diffuse toward each other. At the zone of equivalence, a precipitate is formed. Based on the similarity between the antigen and antibody, different precipitation patterns are formed.

double indirect fluorescent antibody Assay in which an antibody in a patient's serum binds to a known antigen. A second, unlabeled, antihuman antibody is added, and multiple molecules can bind to the patient's antibody. A third fluorochrome-labeled antibody directed against the second antibody is then added.

dual-probe fluorescence resonance energy transfer

(FRET) Real-time polymerase chain reaction (PCR) detection method that uses two probes: one with a donor fluorophore on the 3' end and the other with an acceptor fluorophore on the 5' end. The two probes anneal head-to-tail to accumulated PCR products. Light from the real-time PCR instrument excites the donor fluorescent dye, and this energy is transferred to the acceptor dye by FRET. The acceptor dye then gives off this energy, and it is read by the instrument. As the PCR amplicon accumulates, fluorescence increases.

dysgonic fermenter (DF) Gram-negative fermentative bacillus that has difficulty growing on routine media. At one time, these were referred to by the CDC as *DF-1*, *DF-2*, and *DF-3*; all have now been placed in the genus *Capnocytophaga*.

dysuria Difficulty or painful urination.

E

ecthyma gangrenosum Cutaneous infection most commonly associated with *Pseudomonas aeruginosa* bacteremia.

ectoparasite Organisms that live on, rather than in, the human body; include fleas, lice, ticks, and mites.

- edema factor (EF)** One of three proteins that make up the anthrax toxin. Edema results from the combination of protective antigens with this factor.
- efflux pumps** Proteins located in the bacterial cell membrane that transport molecules out of the cell.
- EI Tor** Strain of *Vibrio cholerae* belonging to the serotype O1.
- electroendosmosis** Movement of buffer ions toward the cathode causing antibody molecules, which have a weak net negative charge, to be carried toward the cathode.
- Elek test** Immunodiffusion test originally described by Elek for detecting the toxin produced by *Corynebacterium diphtheriae*.
- elementary body (EB)** Metabolically inactive infectious form of *Chlamydia*.
- elevation** Description of colony morphology. The elevation should be determined by tilting the culture plate and looking at the side of the colony. Elevation may be raised, convex, flat, umbilicate (depressed center, concave, an “inny”), or umbonate (raised or bulging center, convex, an “outy”).
- Embden-Meyerhof pathway** Energy-yielding pathway converting one molecule of glucose to two molecules of pyruvate; also called the *Embden-Meyerhof-Parnas pathway*.
- emergency response plan** Plan established by each health care setting to deal with the potential of some emergency, such as a bioterror event.
- emerging infection** Infection whose incidence has increased in number of spread geographically in the past few years and could increase in the near future.
- emerging pathogen** Pathogen that is newly recognized, has spread geographically, or has become more virulent.
- emerging zoonosis** Infectious agent that is transmitted from animals to humans and is a newly discovered agent, modified agent, or previously known agent that moves to a new geographic location.
- empiric antimicrobial therapy** Institution of treatment based on practical experience in the absence of culture data.
- employee right-to-know** Occupational Safety and Health Administration laboratory chemical hygiene plan and hazard communication standard (29 CFR 1910.1200, Hazard Communication Standard); states that all clinical laboratory personnel have a need and a right to know the hazards and identities of the chemicals to which they are exposed when working. They also need to know what protective measures are available to prevent adverse effects from occurring.
- empyema** Collection of purulent fluid in the pleural space between the lung and chest wall.
- encapsulated** Strains of bacteria and yeast that produce a capsule.
- encephalitis** Inflammation of the brain.
- endemic relapsing fever** Tickborne relapsing fever caused by *Borrelia* spp.
- endemic spirophilis** Nonvenereal spirochetal disease of the Middle East or Africa caused by *Treponema pallidum* subsp. *endemicum*. Clinical disease closely resembles yaws and is also known as *bejel*.
- endogenous (microbiota)** Originating from within an organism.
- endogenous anaerobe** Anaerobe that exists inside the body of an animal (member of the indigenous microbiota).
- endophthalmitis** Inflammation of the intraocular fluids and tissues.
- endotoxin** Lipopolysaccharide (LPS) component of gram-negative cell walls; composed of lipid A plus core polysaccharide plus O antigen (O polysaccharide side chain); released on lysis of the cell during infection. The lipid A component is responsible for endotoxin activity effects on the host; the O side chain is the antigenic portion of the LPS molecule.
- endotracheal** Within the trachea.
- engineering controls** Controls that isolate or remove a hazard from the workplace.
- enriched media** Media that contain nutritional enhancement to allow growth of fastidious microbes.
- enrichment broth** Liquid medium designed to encourage the growth of small numbers of a particular organism while suppressing other biota present.
- enteric** Member of the order Enterobacterales consisting of organisms that all ferment glucose; almost all fail to produce cytochrome oxidase; almost all reduce nitrates to nitrites. Most are resident biota of the gastrointestinal tract.
- enteric fever** Systemic bacterial infection characterized by diarrhea and prolonged fever; associated with *Salmonella* spp.
- enteritis necroticans** *Clostridium perfringens* type C food poisoning.
- enteroaggregative *Escherichia coli* (EAEC)** Pathogenic *E. coli* strains defined by their attachment to HEp-2 cells; cause persistent pediatric diarrhea.
- enterohemorrhagic *Escherichia coli* (EHEC)** *E. coli* strains producing Shiga toxins, resulting in hemorrhagic diarrhea and colitis and sometimes hemolytic uremic syndrome.
- enteroinvasive *Escherichia coli* (EIEC)** Diarrheagenic *E. coli* strains that invade the intestinal mucosa and cause dysentery similar to that caused by *Shigella* spp.
- enteropathogenic *Escherichia coli* (EPEC)** Diarrheagenic *E. coli* strains that cause severe infantile diarrhea.
- enterotoxigenic *Escherichia coli* (ETEC)** Diarrheagenic *E. coli* strains producing toxins similar to those produced by *Vibrio cholerae*.
- enterotoxin** Protein exotoxin secreted by living or lysed bacteria that alters cell function or damages membranes of the gastrointestinal tract.
- enterotoxin-mediated diarrhea** Diarrheal illness that manifests primarily as a result of the toxin produced by the infecting organism.
- entomophthoromycosis** Chronic subcutaneous form of infection caused by fungi of the order Entomophthorales (present in organic debris—*Conidiobolus coronatus*, *Conidiobolus incongruus*, and *Basidiobolus ranarum* (previously known as *Basidiobolus haptosporus*). It often occurs as the result of traumatic implantation of the organisms in the skin.
- envelope** See **enveloped virus**.
- enveloped virus** Virus surrounded by a phospholipid membrane of host cell origin.
- environmental culture** Culture taken of the environment, such as air, water, or surfaces.
- Environmental Protection Agency (EPA)** Agency of the federal government responsible for regulating environmental pollution and environmental quality.

epidemic relapsing fever Louseborne relapsing fever caused by *Borrelia* spp.

epidemiologic curve Graph plotted during a disease outbreak investigation so the number of events (cases) can be compared with the time of their development.

epididymitis Inflammation of the epididymis affecting men, usually between 19 and 35 years of age; generally a complication of chlamydia or gonorrhea.

epiglottitis Rapidly progressive infection of the epiglottis and adjacent structures usually caused by bacteria.

epitope Specific region of an antigen that binds to an antibody or T-cell receptor; also called an *antigenic determinant*.

Epstein-Barr virus (EBV) Virus that can cause infectious mononucleosis. It primarily infects B cells, where it forms a latent infection that persists for life; also called *human herpesvirus 4* (HHV-4).

erysipelas Acute spreading skin lesion that involves the subcutaneous tissues. The lesion is intensely erythematous, with a plainly demarcated but irregular edge.

erysipeloid Infection in humans caused by *Erysipelothrix rhusiopathiae*.

erythema migrans (EM) Classic target-shaped or bull's-eye skin lesion normally found at the site of a tick bite during infection by *Borrelia burgdorferi*.

erythrasma Skin disease that can result in pink patches, which can turn into brown scales.

erythrocytic phase Part of the life cycle of malaria occurring within red blood cells.

eschar Dark area where necrosis occurs in the center of a necrotic lesion; a scab; characteristically seen in patients with cutaneous anthrax.

Escherichia-Citrobacter-like organism Organism that produces a dry, pink colony with a surrounding halo of pink, precipitated bile salts.

Etest Commercial minimal inhibitory concentration (MIC) test that uses plastic strips impregnated with a gradient of antimicrobial concentrations. The strips are placed on an agar plate that has been inoculated with the test bacteria; following overnight incubation, the MIC is noted where the ellipse intersects the scale imprinted on the top of the strip.

etiologic agent Microorganism or virus causing a disease.

eugonic fermenter (EF) Gram-negative bacillus or coccobacillus that ferments glucose or other carbohydrates; grows on routine media, as compared with dysgonic fermenters, which do not grow on routine media. The designation *EF* means that it has yet to be placed into a specific genus.

eugonic oxidizer Gram-negative bacillus or coccobacillus that does not ferment glucose but can oxidize it; grows on routine media but is not yet placed into a specific genus.

eukarya See *eukaryote*.

eukaryote Organism with complex cell (cells); structures in which the genetic material is organized into a membrane-bound nucleus (nuclei), and other organelles.

eumycotic mycetoma Mycetoma caused by fungal organisms, usually comprised of wide septate hyphae.

exanthem Eruptive disease, especially one accompanied by fever, such as smallpox or measles.

exfoliative toxin Toxin that affects the epidermal layers of the skin. Also known as epidermolytic toxin associated with staphylococcal scalded skin syndrome.

exoerythrocytic phase Part of the life cycle of malaria that begins when the sporozoites are injected into humans from the mosquito. The sporozoites first invade liver cells.

exogenous Originating outside of an organism, as opposed to an endogenous agent.

exogenous anaerobe Anaerobe that exists outside of the body.

exopolysaccharide (EPS) Carbohydrate substance secreted by a number of microorganisms; used for attachment and is a major component of biofilms.

exotoxin Toxic protein produced by a bacterium and released into its environment; may exert adverse effects quite remote from the site of infection.

expectorated sputum Material from the lower respiratory tract produced by a deep cough.

exposure control plan OSHA Bloodborne Pathogen Standard safety requirement that the employer must have in place to protect the employee from bloodborne pathogens; must be annually reviewed and updated and available to all employees.

extended-care facility (ECF) Facilities in which patients are frequently immunosuppressed by disease, age, or therapy. Extended-care settings include skilled nursing facilities, nursing homes, assisted living centers, rehabilitation centers, and hospice care settings.

extended-spectrum β -lactamase (ESBL) β -Lactamase produced by *Escherichia coli*, *Klebsiella* spp., *Proteus mirabilis*, and other members of the order Enterobacterales that hydrolyze and render inactive penicillins, cephalosporins, and aztreonam.

F

facilitator Person with no vested interest in a problem whose role is to use problem-solving skills and experience to help team members resolve a problem.

facultative anaerobe Microorganism that does not require oxygen for growth but will use oxygen and grow better if it is present.

false-negative Negative test result in an individual with the disease in question.

false-positive Positive test result in an individual without the disease in question.

family In biological classification, a rank or a taxon in the rank between an order and genus.

fast-acting antiseptic Phrase used to describe an antimicrobial that exhibits the most rapid action of antiseptics; usually the rapid action of antiseptic is expressed in seconds to minutes.

fastidious Hard to grow; requires additional growth factors.

fecal leukocytes White blood cells found in stool.

fermentation Process in which a molecule is oxidized to produce energy without an exogenous electron acceptor; often used by cells when oxygen is unavailable.

fermentative Bacteria that are able to use glucose or other carbohydrates in the absence of oxygen by using an organic molecule as a final electron acceptor.

filamentous Composed of or containing filaments.

filamentous hemagglutinin Virulence factor of certain *Bordetella* spp. believed to facilitate attachment of bacteria to ciliated epithelial cells.

filariform larva Larval stage infective for the definitive host.

filtration Passing liquids through thin membrane filters composed of plastic polymers or cellulose esters containing pores of a certain size. The liquid is pulled (vacuum) or pushed (pressure) through the filter matrix. Organisms larger than the size of the pores are retained; air filtration using high-efficiency particulate air filters.

fimbria (pl. fimbriae) Nonflagellar, sticky, proteinaceous, hairlike appendage that adheres some bacterial cells to each other and to environmental surfaces.

Fitz-Hugh-Curtis syndrome Perihepatitis occurring as a complication of *Neisseria gonorrhoeae* infection; characterized by fever, upper quadrant pain, and tenderness and spasm of the abdomen.

flagella Exterior protein filaments that rotate; used by microorganisms for motility.

fluorescein isothiocyanate Fluorescent molecule commonly bound to antibody and used in diagnostic tests.

fluorescence resonance energy transfer (FRET) FRET occurs between two dye molecules held in very close proximity to each other. One dye is a donor, the other an acceptor. Two dyes may be used in conjunction to generate fluorescence, as in dual-probe FRET, or a fluorescent dye and quenching molecule may be used in conjunction to keep fluorescence low until the two molecules are separated from each other, as in the 5' nuclease assay.

fluorochrome Chemical used in fluorescent immunoassays that absorbs light of one wavelength and emits light of a different wavelength.

fluorogenic substrate Nonfluorescent molecule that becomes fluorescent when cleaved by a specific enzyme.

fluorophore Fluorescent dye molecule attached to probes used in molecular assays.

focused monitors Process created to monitor a suspected problem.

folliculitis Inflammation involving the hair follicles as a result of infection or irritation.

fomite Nonliving object that can carry or transmit infectious particles.

Food and Drug Administration (FDA), U.S. Federal agency in the U.S. Department of Health and Human Services established to regulate the release of new foods, drugs, medical devices, and other health-related products.

fungemia Fungal invasion of the bloodstream.

furuncle Painful swollen area on the skin caused by a staphylococcal infection that involves a hair follicle; also called a boil.

fusiform Spindle-shaped or tapered at each end.

G

β -galactosidase Enzyme capable of hydrolyzing lactose to glucose and galactose.

β -galactoside permease Bacterial membrane protein facilitating the uptake of β -galactosides.

gamete One of two cells, a male and a female, whose union is necessary in sexual reproduction.

gametocyte The sexual cell of Apicomplexa; the female (macrogametocyte) and male (microgametocyte) that develop into gametes.

gas gangrene Bacterial infection that produces gas within tissues; may lead to myonecrosis and sepsis; a medical emergency.

gelatinase Proteolytic enzyme that breaks down gelatin to amino acids.

genital herpes Viral infection in the genitals caused by herpes simplex virus.

genital ulcer disease (GUD) Group of sexually transmitted diseases causing ulcers on the genital area, such as syphilis and genital herpes.

genotype Genetic makeup of an organism.

genus In biological classification, a rank or a taxon in the rank between a family and species.

germ theory of disease Theory that all infectious diseases are caused by the activity of microorganisms.

germ tube Tubelike projection from a blastoconidium or spore, without a constriction at its base.

glanders Disease caused by *Burkholderia mallei*.

glycolysis Sequence of reactions that converts glucose into pyruvate, with the concomitant production of a relatively small amount of adenosine triphosphate. Glycolysis can be carried out anaerobically (in the absence of oxygen) and is thus an especially important pathway for organisms that can ferment sugars.

glycopeptide Class of antibiotic drugs that consists of glycosylated cyclic or polycyclic peptides, such as vancomycin and teicoplanin. This class of antibiotics inhibits the synthesis of cell walls in susceptible microbes by inhibiting peptidoglycan synthesis.

glycylcycline Class of antibiotic drugs derived from the tetracyclines. Similar to tetracyclines, this class of antibiotics binds to the 30S ribosomal subunit to prevent the aminoacyl tRNA from binding to the A site of the ribosome.

gonorrhea Sexually transmitted disease caused by the bacterium *Neisseria gonorrhoeae*.

gonorrheal ophthalmia neonatorum Caused by *Neisseria gonorrhoeae*, a form of conjunctivitis acquired by a newborn during birth when the infant's eyes are contaminated during passage through the birth canal of a mother infected with *N. gonorrhoeae*. *Chlamydia trachomatis* can produce a similar infection.

gram-negative bacteria Bacteria that do not retain the crystal violet complex; stained red by the safranin counterstain.

gram-negative intracellular diplococci (GNID) Gram-negative cocci in pairs found inside a phagocyte or polymorphonuclear cell.

gram-positive bacteria Bacteria that retain the crystal violet-iodine complex and appear blue on Gram-stained smears.

Gram stain Method of staining microorganisms using a violet stain, followed by an iodine solution, decolorizing with an alcohol or acetone solution, and counterstaining with safranin. The retention of the violet color of the stain or the pink color of the counterstain serves as a primary means of identifying and classifying bacteria.

granulocytopenia Disorder characterized by an abnormally low concentration of granulocytes in the blood.

granuloma An aggregate of immune cells that forms in response to a persistent inflammatory stimulus; can be contained in a fibrotic capsule.

granuloma inguinale Genital ulcerative disease caused by the intracellular gram-negative bacterium *Klebsiella granulomatis* (formerly *Calymmatobacterium granulomatis*); also called *donovanosis*.

granulomatous amebic encephalitis (GAE) An infection of the brain caused by the free-living amebae *Acanthamoeba* spp. and *Balamuthia mandrillaris*.

GRASE Term used to describe nonprescription drug products that are “generally recognized as safe and effective.”

gummas Granulomatous lesions in skin, bones, and liver; clinical manifestation of tertiary syphilis.

H

H antigen Flagellar antigen.

HACEK Specific species of the genera *Haemophilus*, *Aggregatibacter* (*Actinobacillus*), *Cardiobacterium*, *Eikenella*, and *Kingella* have been grouped together to form the acronym HACEK (first letter of each genus).

halophile Salt-loving; an organism that grows best in media or environment with an increased concentration of NaCl.

hand hygiene Refers to techniques used to ensure that hands are clean and microbe-free. Hand hygiene involves washing with soap and water if the hands are soiled or using alcohol hand rubs if the hands are not soiled.

health care antiseptic drug product Antiseptic-containing drug product applied topically to the skin to help prevent infection or prevent cross-contamination.

health care personnel hand wash Antiseptic-containing preparation designed for frequent use; reduces the number of transient microorganisms on intact skin to an initial baseline level after adequate washing, rinsing, and drying; broad-spectrum, fast-acting, and, if possible, persistent.

healthcare-associated bacteremia Bacteria in the bloodstream of patients who are hospitalized or living in a nursing home or other facility.

healthcare-associated, community-onset methicillin-resistant *Staphylococcus aureus* (HACO-MRSA) See methicillin-resistant *Staphylococcus aureus* (MRSA).

healthcare-associated infection (HAI) Infection acquired in a health care setting.

hemagglutinin Glycoprotein antigen on influenza viruses that facilitates attachment of the virus to susceptible host cells. The antigen also gets its name from its ability to clump erythrocytes.

α -hemolysin Cytolytic toxin produced by *Staphylococcus aureus* that can damage erythrocytes, platelets, and macrophages.

β -hemolysin Cytolytic toxin, also known as *sphingomyelinase C*, that acts on the sphingomyelin membrane component of erythrocytes.

hemolysis *Lysis* pertains to dissolution or breaking apart; *hemo* pertains to red blood cells. A reaction, especially caused by enzymatic or toxin activity of bacteria, observed in the medium immediately surrounding or underneath the colony.

α -hemolysis Partial lysing of erythrocytes in a blood agar plate around and under the colony; results in a green discoloration of the medium.

β -hemolysis Complete clearing of erythrocytes in a blood agar plate around or under the colonies caused by the complete lysis of red blood cells.

hemolytic-uremic syndrome (HUS) Clinical syndrome characterized by the destruction of red blood cells, damage to the lining of blood vessel walls, and in severe cases, kidney failure.

hepatitis Inflammation of the liver. Can be caused by any of the hepatitis viruses, chemicals, drugs, alcohol, or certain genetic disorders. The hepatitis viruses can be transmitted in different ways: contact with human blood, sexually, and the fecal-oral route.

heterophile antibody Antibody produced in an individual in response to one immunogen that can also bind to a different but similar molecule (antigen).

heteroploid Cells that contain an abnormal and variable number of chromosomes that is not a multiple of the normal haploid number.

heteroresistant Population of cells in which some cells appear susceptible and others appear resistant.

heterotroph Organism that requires organic substrates as a source of carbon for metabolism.

hexacanth embryo (oncosphere) First larval stage of most tapeworms found within the egg, characterized by the presence of six hooklets.

hidradenitis suppurativa Skin disease that affects areas that maintain apocrine sweat glands and hair follicles, such as the axillae, groin, and buttocks and under the breasts of women.

high-level aminoglycoside resistance In enterococci, indicates resistance to high concentrations of aminoglycosides (e.g., gentamicin or streptomycin) that usually result from production of aminoglycoside-modifying enzymes. Enterococci with high-level gentamicin resistance do not show synergism with ampicillin, penicillin, or vancomycin; streptomycin performs similarly.

highly active antiretroviral therapy (HAART) Therapy that, when properly prescribed and used, can improve the quality of life and longevity of those infected with human immunodeficiency virus, although it does not cure the infection.

hippurate hydrolysis Test used for the presumptive identification of group B streptococci (*Streptococcus agalactiae*). The hippuricase enzyme found in group B streptococci hydrolyzes sodium hippurate to sodium benzoate and glycine.

Hodgkin disease (HD) Type of lymphoma characterized by swollen lymph nodes and the presence of large malignant cells called *Reed-Sternberg cells*, which are multinucleated or have a bilobed nucleus (resembling an owl's eye) with prominent eosinophilic inclusion-like nucleoli.

homogenization Preparation of tissue for microbiology culture by grinding to release microbes from cells and produce an even suspension.

hospital-associated methicillin-resistant *Staphylococcus aureus* (HA-MRSA) See methicillin-resistant *Staphylococcus aureus* (MRSA).

housekeeping gene Gene that codes for basic functional proteins for cells. They are always expressed. They are good targets for internal controls from clinical specimens.

human blood bilayer Tween (HBT) agar Medium of choice for the isolation and presumptive identification of *Gardnerella vaginalis*.

human granulocytic anaplasmosis (HGA) Infectious disease caused by *Anaplasma phagocytophilum* (formerly known as *Ehrlichia phagocytophilum*). The symptoms closely resemble those of human monocytic ehrlichiosis. See **human monocytic ehrlichiosis**.

human immunodeficiency virus (HIV) Retrovirus that infects components of the human immune system, primarily CD4⁺ T cells, macrophages, and dendritic cells.

human monocytic ehrlichiosis (HME) Disease caused by *Ehrlichia chaffeensis*.

human papillomavirus (HPV) A virus that causes the most common sexually transmitted viral disease in the United States, genital warts. Certain genotypes cause various forms of cancer in the genital area, particularly in the cervix.

humoral immune response See **humoral-mediated immunity**.

humoral-mediated immunity Type of immune response that involves circulating antibodies.

hyaluronidase Enzyme, also referred to as *spreading factor*, that solubilizes the ground substance of mammalian connective tissues (hyaluronic acid).

hybrid capture Signal amplification method. An RNA probe is annealed to target DNA; a capture antibody binds the DNA-RNA hybrid to a solid surface. A probe labeled with alkaline phosphatase (AP) then anneals to the hybrid, and the AP substrate is added to the system; cleavage of the substrate results in light emission, detected by a luminometer.

hybridoma Cell formed from the fusion of a normal B cell to a myeloma cell, a cancerous plasma cell, so the resulting cell is able to secrete monoclonal antibodies and is immortal.

hydroxyl radical (OH⁻) An intermediate reactive generated when the superoxide anion reacts with hydrogen peroxide in the presence of iron (Fe³⁺/Fe²⁺). Short-lived molecule that is the most potent biological oxidant known.

hypha (pl. hyphae) Long strand of fungal cells, with or without cross walls; filaments interweave to form mats called *mycelia*.

I

iatrogenic Pertains to an event caused by a medical intervention.

iatrogenic infection Infectious condition caused by a medical intervention.

immune complex Combination of antigen and antibody bound together.

immune response Resultant action of the immune system, such as antibody production to an immunogen; response of the immune system to an antigen.

immune system Organ system that protects an organism from outside biological influences.

immunocompetent Term used to describe the ability of an immune system to mobilize and deploy its antibodies and other responses to stimulation by an immunogen.

immunocompromised Term used to describe an individual with deficient function of the immune system.

immunocompromised hosts See **immunocompromised**.

immunodiffusion Movement of antigens or antibodies through a matrix, such as agarose.

immunogen Molecules capable of stimulating an immune response.

immunoglobulin Complex group of serum proteins produced by B cells and plasma cells in response to foreign immunogens. In humans there are five isotypes: IgG, IgM, IgA, IgD, and IgE.

immunoglobulin A (IgA) Antibody defined by the α heavy chain. This is the immunoglobulin found in greatest concentration in secretions.

immunoglobulin D (IgD) Antibody defined by the δ heavy chain.

immunoglobulin E (IgE) Antibody defined by the ϵ heavy chain. IgE is primarily attached to mast cells and serves as the antigen recognition for type I hypersensitivity reactions to allergens and immunity to parasites.

immunoglobulin G (IgG) Antibody defined by the γ heavy chain. This is the primary immunoglobulin found in human serum.

immunoglobulin M (IgM) Antibody defined by the μ heavy chain. Found in human serum as a pentamer, but monomers are embedded into mature B-cell membranes.

immunosenescence Naïve T cells are no longer available to be stimulated by immunogens, which leads to the decline of the immune response over time.

immunosuppression Term used to describe the state of an immune system that is suppressed.

impetigo Localized skin disease that begins as small vesicles and progresses to weeping lesions.

in situ amplification (ISA) Technique that couples polymerase chain reaction amplification with in situ hybridization. The method is used to amplify DNA directly from tissue specimens, intact cells, or chromosomal material; used to increase the sensitivity and specificity of in situ hybridization reactions.

in situ hybridization Hybridization method in which target DNA or RNA is detected directly in intact cells, tissue, or chromosomal material with a labeled probe.

incidence Number of new cases of a disease over a time period (e.g., weeks, months, years).

index case First case in an outbreak investigation.

indifference Occurs when the antimicrobial activity of a combination of antimicrobial agents is equal to the activity of the individual agents.

indigenous microbiota Microorganisms of low virulence normally found in or on body sites; synonymous with *usual microbiota*.

indirect agglutination Agglutination assay in which an antigen is artificially attached to a carrier particle, such as latex beads.

indirect fluorescent antibody test Immunoassay using a known antigen affixed to a microscope slide that binds antibody in patient's serum. A second fluorochrome-labeled, antihuman antibody is then added.

indirect sandwich immunoassay Immunoassay using a known antigen affixed to a solid surface that binds antibody in patient's serum. A second labeled antihuman antibody is then added.

individualized quality control plan (IQCP) An all-inclusive approach to assuring quality. It includes many practices that a laboratory uses to ensure quality testing. An IQCP must address the potential failures and errors identified in the entire testing process: preanalytic, analytic, and postanalytic phases of testing.

indole test Bacteriologic test to determine an organism's ability to form indole from tryptophan with the enzyme tryptophanase.

induced resistance Resistance to a compound caused by induction by the antimicrobial agent itself, resulting in differential resistance gene expression.

induced sputum Material from the lower respiratory tract collected following aerosol induction.

infection control risk assessment (ICRA) Review of a situation, such as new construction, to determine any infection control risks that may be present.

infection prevention and control (IPC) A practical, evidence-based approach to prevent patients and health care workers from being harmed by avoidable infection.

infection prevention and control practitioner (IPCP) Individual in a health care setting whose responsibility is to institute outbreak investigations, develop procedures to prevent the acquisition of infections, and implement infection control practices.

infection preventionist See **infection prevention and control practitioner**.

infection rate Occurrence of infections within a given at-risk population, expressed as a percentage or as a rate.

inflammation Physiologic reaction of vascularized tissue to injury involving physical symptoms of pain, redness, swelling, and tenderness caused by accumulation of plasma and white blood cells; part of innate immunity.

inhalation anthrax Form of anthrax that results from inhaling anthrax spores. This is the most likely form of anthrax that would result from a release of anthrax spores into the air.

innate immune response See **innate immunity**.

innate immune system See **innate immunity**.

innate immunity Natural form of host protection; nonspecific and not stimulated by specific antigenic stimuli.

insertion sequence (IS) Mobile genetic elements known to encode only functions involved in insertion events.

integron Mobile DNA element that can capture and carry genes, especially those that carry antimicrobial drug resistance.

interferon (IFN) Class of mediators that increases the resistance of cells to viral infection by inhibiting viral replication and the growth of some euplastic cells.

interleukin (IL) Type of cytokine originally thought to be produced by and to act on leukocytes; however, it has since been discovered that other types of cells can elaborate some interleukins and that interleukins also have effects on cells other than leukocytes.

intermediate Refers to the interpretation of antimicrobial susceptibility test results implying that the agent might be effective for infections located at body sites where the drugs are physiologically concentrated, or when a high dosage of drug can be used. The intermediate category also includes a buffer zone,

which should prevent small, uncontrolled technical factors from causing major discrepancies in interpretation.

intermediate host Individual in which a parasite has its larval and or asexual reproductive stage.

intermittent bacteremia When organisms are periodically released from the primary site of infection into the bloodstream. This occurs as the result of abscesses or as a clinical manifestation of certain types of infections.

intertrigo Yeast infection of skin folds caused by *Candida albicans*.

intervention Implementation of procedures to stop the spread of an infection or outbreak.

intravascular device Device such as a catheter that is inserted into a blood vessel.

intrinsic resistance Type of antimicrobial resistance; an inherent genotypic characteristic disseminated horizontally to progeny. Mechanisms that mediate intrinsic resistance to antimicrobials include cell wall impermeability, efflux, biofilm formation, and expression of genes mediating inactivating enzymes.

isolation streak Technique to spread inoculum over the surface of agar plates so individual colonies can be obtained and semi-quantitative analysis performed.

J

Jarisch-Herxheimer reaction Systemic reaction of fever, chills, headache, myalgias, and exacerbation of cutaneous lesions believed to be caused by the rapid release of endotoxin from organisms shortly after initiation of antimicrobial therapy.

JEMBEC (James E. Martin Biological Environmental Chamber) system Commercial system for collection of specimens for *Neisseria gonorrhoeae*; contains selective agar and a CO₂-generating tablet.

K

K antigen Capsular surface antigen possessed by some strains of Enterobacterales, particularly *Salmonella enterica* serotype Typhi, in which it is called the *Vi antigen*.

Kanagawa phenomenon Refers to heat-stable hemolysin production by most strains of *Vibrio parahaemolyticus*, able to lyse human red blood cells in a special, high-salt, mannitol medium (Wagatsuma agar). Production of β -hemolysis on this agar is called the *Kanagawa phenomenon*.

karyosome Spherical chromatin mass within the nucleus of protozoa.

keratitis Inflammation of the surface or connective tissues of the cornea.

keratoconjunctivitis Inflammation of the ocular external surfaces (conjunctiva and cornea epithelia).

ketolide Semi-synthetic derivative of 14-member ring macrolides; has a carbonyl group at the C3 position, which is crucial in conferring sensitivity to macrolide-resistant strains. Ketolides share many of the characteristics of the advanced macrolides.

kinetoplast Structure found in some blood and tissue protozoans composed of a granule, from which the flagellum or undulating membrane arises, and a mitochondrion.

Kinyoun stain Acid-fast stain used to visualize mycobacteria and certain coccidian parasites. Like the Ziehl-Neelson stain, the Kinyoun stain is a carbolfuchsin method; however, it does not involve heat application.

Kirby-Bauer test Type of antimicrobial susceptibility test in which filter paper disks impregnated with antimicrobial agents are placed on the surface of an agar plate that has been inoculated with the test bacteria. Following overnight incubation, zones of inhibition of growth are measured; results for each agent tested are interpreted as susceptible, intermediate, or resistant based on predefined Clinical and Laboratory Standards Institute criteria; also referred to as *antimicrobial disk diffusion test*.

Klebsiella-Enterobacter-like organisms Organisms that produce large, mucoid, pink colonies; occasionally have cream-colored centers.

Kligler iron agar (KIA) Bacteriologic medium that aids in determining carbohydrate fermentation (glucose and lactose) and H₂S formation.

Koplik spots White spots that appear on the mucous membranes of measles patients approximately 1 day before the appearance of the typical measles rash.

Krebs cycle A series of enzyme catalyzed reactions that reduce the acetyl portion of acetyl coenzyme A; also referred to as the *tricarboxylic acid cycle*.

L

L form Bacterium that has temporarily lost its cell wall as a result of environmental conditions.

laboratory-acquired infection (LAI) An infection occurring as a result of laboratory-related activities.

Laboratory Response Network—Biological

(LRN-B) National program for detection and identification of biothreat agents.

β-lactam antibiotic Antibiotic that contains the β-lactam ring, the structure essential for the antibacterial activity of the antibiotic in this class.

β-lactam ring Structure found in penicillins, cephalosporins, monobactams, and carbapenems. This four-member ring functions as a structural analogue of the normal substrate acyl-D-alanyl-D-alanine.

β-lactamase Enzyme produced by bacteria that destroys the activity of β-lactam agents by hydrolyzing the β-lactam ring portion of the β-lactam molecule; many types of β-lactamase affect specific β-lactam agents.

β-lactamase inhibitor (BLI) Molecule that inactivates the enzyme activity of β-lactamases preventing them from destroying the β-lactam ring found in some antibiotics.

lactoferrin Multifunctional protein with antimicrobial activity that is one of the innate defense proteins found mainly in mucosal secretions such as tears. This protein is present in secondary granules of polymorphonuclear neutrophils. It belongs to the transferrin family of proteins showing a high affinity for iron (ferric state).

lactose fermenters Bacteria able to metabolize lactose without oxygen typically forming acid end products. Easily detected by the color change they produce on media; as the pH changes when lactose is fermented, the organisms produce colored colonies, depending on the pH indicator. Colonies of nonfermenters remain clear and colorless.

Lancefield classification Classification of streptococci based on a surface antigen, the C carbohydrate.

latent phase In syphilis, the period in late syphilis when it passes into a silent period (asymptomatic), which may last for many years.

Lean A quality improvement tool to minimize waste and at the same time maximize customer value.

Learn from Defect A process quality improvement tool to evaluate risks; provides a methodical and structured approach to ensure that every component of the process is assessed.

Legionnaires' disease Febrile disease with pneumonia (atypical) caused by *Legionella* organisms.

leprosy Infection of the skin, mucous membranes, and peripheral nerves caused by *Mycobacterium leprae*.

leptospirosis Zoonotic disease in humans caused by *Leptospira interrogans*.

lethal factor One of three proteins that make up the anthrax toxin. The combination of lethal factor with protective antigen results in cell death.

leucine aminopeptidase (LAP) Enzyme used in the test for presumptive identification of streptococci. It is a peptidase that hydrolyzes peptide bonds adjacent to a free amino group; called *LAP* because it reacts most quickly with leucine.

leukocidin Toxin secreted by certain bacterial species toxic to leukocytes (e.g., Panton-Valentine leukocidin produced by *Staphylococcus aureus*).

linezolid Antibiotic thought to bind to the 50S ribosomal subunit of prokaryotes, preventing formation of the preinitiation complex, with the 30S ribosomal subunit containing bound initiation factors.

lipooligosaccharide (LOS) Glycolipid consisting of lipid A and core structures similar to lipopolysaccharide. LOS is found in the cell wall of some gram-negative bacteria including *Neisseria*, *Campylobacter*, and *Haemophilus* species.

lobomycosis Chronic fungal infection of the skin caused by *Lacazia loboi* (previously known as *Loboa loboi*); mainly found in the tropics of South America and Central America. The organisms are thought to reside in soil or vegetation and infect humans via skin trauma.

Loeffler medium (Loeffler agar) Nonselective medium containing serum; generally used for growing *Corynebacterium* spp.

Löwenstein-Jensen medium Egg-based, opaque, solid medium commonly used in clinical laboratories for growth of mycobacteria.

Lyme borreliosis Systemic, multistage illness (Lyme disease) caused by *Borrelia burgdorferi* infection following a tick bite.

lymphocyte Type of white blood cell that develops in the bone marrow but matures in other areas such as the thymus, spleen, and lymph nodes.

lymphogranuloma venereum (LGV) Severe, invasive, sexually transmitted disease associated with specific serovars (L1, L2, L2a, L3) of *Chlamydia trachomatis*.

lymphokine Chemical messenger produced by lymphocytes that carry messages among the cells of the immune system. Examples include interferon, which initiates defensive

reactions to viruses, and the interleukins, which activate specific immune cells.

lysine iron agar (LIA) Bacteriologic medium determining lysine metabolism and the ability to produce H_2S .

lysogeny Incorporation of the genetic material of a bacteriophage with that of the host bacterium.

lysozyme Enzyme that destroys bacterial cell walls by hydrolyzing the polysaccharide component of the cell wall. Lysozyme can be found in the mucosal membranes that line the human nasal cavity and tear ducts.

M

M protein Antigen found in the cell wall of *Streptococcus pyogenes* that is important for virulence (attachment) and is not found in the other Lancefield group streptococci.

macroconidium Larger of two types of conidia produced by fungi, typically multicelled.

macrolide Class of antibiotic drugs, such as erythromycin, clarithromycin, and azithromycin, that targets the 50S subunit specifically by binding to the peptidyltransferase cavity in the proximity of the A and P loops, near adenine 2058 of 23S rRNA.

macroscopic observation Gross appearance or physical characteristics of the specimen.

major outer membrane protein (MOMP) Predominant protein present in the outer membrane of bacteria. These proteins often exhibit antigenic variation, allowing serogrouping of bacteria, such as with *Chlamydia trachomatis*.

margin Border, or edge.

material safety data sheet (MSDS) Information provided by the manufacturer or distributor for hazardous chemicals.

matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry Mass spectrometry approach that includes the use of molecular and mass spectrometry methods to examine protein profiles; expected to increase the ability to identify clinically relevant microorganisms accurately and rapidly.

Maurer dots Coarse granulations present in red blood cells invaded by the parasite *Plasmodium falciparum*.

McFarland turbidity standards Suspensions of latex particles or barium sulfate prepared at various densities to represent specific numbers of bacteria. For example, the turbidity of a McFarland 0.5 standard is comparable to the turbidity of a bacterial suspension containing 1.5×10^8 colony-forming units/mL.

mecA Gene that codes for penicillin-binding protein 2a, which confers oxacillin resistance in staphylococci.

median infectious dose (ID_{50}) Average amount or number of organisms that will cause an infection in 50% of those who acquire the organism.

mediastinitis Clinical condition characterized by widening of the mediastinum, the central compartment of the thoracic cavity. Although not specific for anthrax, it is a common radiologic finding in patients with inhalation anthrax.

medusa head Term used to describe the colony appearance of *Bacillus anthracis*.

melioidosis Disease caused by *Burkholderia pseudomallei*.

melting curve analysis Real-time polymerase chain reaction (PCR) method used to determine whether nonspecific PCR products or primer-dimers have formed; also used to

determine the identity of a target. Fluorescence is observed in real-time PCR when a fluorophore is annealed to a PCR product. When the temperature of an assay is increased for melting curve analysis, the fluorophore will be released from the PCR product by denaturation. This causes a sudden decrease in fluorescence, which can be read as a peak—the temperature at which a fluorophore is released from the target sequence.

melting temperature (T_m) Temperature at which a double-stranded nucleic acid molecule is 50% hybridized and 50% dissociated. A temperature below the T_m is often used for hybridization reactions, including the polymerase chain reaction.

meningismus Clinical manifestation characterized by nuchal rigidity, headache, and photophobia, without the presence of inflammation or infection but seen in concordance with other acute illnesses in children.

meningitis (leptomeningitis) Inflammation of the meninges, the protective membrane covering the brain and spinal cord. Although the swelling may be caused by a bacterial or viral infection of the membrane that surrounds the brain and spinal cord, injuries, cancer, and other types of infections may also cause meningitis.

meningococcemia Presence of meningococci (*Neisseria meningitidis*) in the bloodstream.

meningoencephalitis Presence of inflammation in the meninges and the brain.

merozoite Parasitic form produced during schizogony. In malaria, these structures are released from a ruptured erythrocyte and invade other erythrocytes at the end of an asexual reproductive cycle. Some merozoites differentiate into gametocytes.

mesophile Organism that grows best in moderate temperatures, 25° to 40° C.

metacercaria For most flukes, this is the life-cycle stage infective for humans. It develops after the cercaria invades the tissue of the second intermediate host or contacts water or vegetation, loses its tail, and develops a protective wall.

metagenomics Study (genomic analysis) of the genetic material of all microorganisms recovered directly from environmental samples using molecular techniques.

methicillin-resistant *Staphylococcus aureus* (MRSA) Strain of *S. aureus* that contains *mecA* and PBP2a and is resistant to methicillin and other β -lactamase-resistant penicillins such as oxacillin or nafcillin.

methicillin-resistant *Staphylococcus epidermidis* (MRSE) Strain of *S. epidermidis* that is resistant to methicillin and other β -lactamase-resistant penicillins such as oxacillin or nafcillin.

methicillin-sensitive *Staphylococcus aureus* (MSSA) Strain of *S. aureus* that is easier to treat than MRSA because it is susceptible to methicillin and other β -lactamase-resistant penicillins such as oxacillin or nafcillin.

methicillin-susceptible *Staphylococcus aureus* (MSSA) Strain of *Staphylococcus aureus* susceptible to methicillin and other β -lactamase-resistant penicillins such as oxacillin or nafcillin.

methyl red–Voges-Proskauer (MRVP) test Bacteriologic test determining the end products of glucose fermentation: methyl red test, mixed acids; Voges-Proskauer test, stable neutral products.

- microaerophile** Microorganism that grows in conditions of reduced oxygen and increased carbon dioxide.
- microaerophilic** Term used to describe microorganisms that require environments containing a concentration of oxygen lower than that present in the atmosphere (about 20%).
- microbial load** Total number of organisms present (bioburden).
- microbial morphology (morphotypes)** Description of microorganisms, their size, shape, internal structure and other characteristic features that help recognize them. Gram-positive cocci in pairs, tetrads, and grapelike clusters are a staphylococcal morphotype.
- microbiota** Microscopic organisms of a region (e.g., respiratory, urinary, gastrointestinal tract) harbored by normal, healthy individuals.
- microconidium** Smaller of two types of conidia produced by fungi; usually single-celled, rarely two-celled.
- microfilaria** Larval form of filarial worms.
- Middlebrook 7H10 and 7H11 agars** Serum albumin-based clear agar media used to support the growth of mycobacteria.
- miliary tuberculosis** Disseminated disease due to the hematogenous spread of tubercle bacilli, often fatal.
- minimal bactericidal concentration (MBC)** Lowest concentration of antimicrobial agent that kills 99.9% of the test bacteria.
- minimal inhibitory concentration (MIC)** Lowest concentration of antimicrobial agent that inhibits the growth of a bacterium.
- minimal medium** Laboratory growth medium whose contents are simple and defined; not generally used in the diagnostic microbiology laboratory.
- miracidium (pl. miracidia)** First-stage, ciliated, free-swimming larva of flukes that emerges from the egg and penetrates a specific species of snail to continue the fluke life cycle.
- Moeller decarboxylase base medium** Classic bacteriologic medium used to detect decarboxylase activity.
- moist heat** High temperature used with water to kill microorganisms. Heat under steam pressure; e.g., autoclaves.
- mold** Fungus characterized by hyphae; also known as *filamentous fungi*.
- molecular beacons** Real-time polymerase chain reaction (PCR) detection technique. A molecular beacon probe is a hairpin loop structure, with a fluorophore on the 5' end and a quencher on the 3' end. During the denaturation step of PCR, the molecular beacon probe dissociates, as does formed PCR product. The probe anneals to the PCR product; when this occurs, the fluorophore and quencher are no longer in close proximity. Fluorescence thus increases as the PCR product accumulates.
- molecular epidemiology** The analysis of molecules, such as proteins and nucleic acids, for the detection, identification, and characterization of microorganisms to generate isolate-specific markers to assess epidemiologic relatedness.
- molluscum contagiosum** Common skin disease caused by a poxvirus (molluscum contagiosum virus); characterized by small, firm, waxy papules, often with umbilicated centers; occasionally giant lesions may be seen.
- monoclonal antibody** Antibody solution with specificity to a single epitope.
- monograph** Developed for therapeutic classes of ingredients generally recognized as safe and effective. A manufacturer wanting to market a product containing an ingredient covered under the over-the-counter monograph need not seek the U.S. Food and Drug Administration's prior approval.
- monomicrobial** One microbe morphotype is present; if it is the likely pathogen in an infection, the infection is monomicrobial.
- morula (pl. morulae)** Intracellular inclusion suggestive of infection with *Ehrlichia* spp.
- motility-indole-ornithine (MIO) medium** Bacteriologic medium determining motility, the ability to form indole from tryptophan, and ornithine metabolism.
- mRNA translation** Messenger RNA that encodes and carries information from DNA during transcription to sites of protein synthesis (ribosomes) to undergo translation to yield a gene product. Translation is a step in the process of protein biosynthesis.
- multilocus enzyme electrophoresis (MLEE)** Nonamplified strain-typing method. Proteins are isolated from the strain of interest and separated in a gel. A probe is then used to detect a specific protein. Differences in protein migration patterns are mutations; different strains can be identified this way.
- multilocus sequence typing (MLST)** Strain-typing method that uses polymerase chain reaction to amplify several different genetic loci. The resulting fragments are separated by electrophoresis and analyzed. The same strain will have the same pattern.
- multilocus variable-number of tandem repeat analysis (MLVA)** Typing method that takes advantage of repetitive DNA sequences in genomes. MLVA amplifies regions of DNA that contain repeats. When there are different numbers of repeats at a given locus, it is referred to as a variable number of tandem repeats (VNTR). MLVA maps VNTRs among bacterial strains by using the polymerase chain reaction assay.
- multiplex polymerase chain reaction (PCR)** PCR method that uses two primer sets in the same tube. Each primer set is specific for a different target.
- mutualism** A symbiotic relationship when both species benefit from the association.
- mycelia** Intertwined hyphae that form a mat on the surface of a fungal colony; aerial mycelia grow upward away from the surface.
- mycetoma** Granulomatous subcutaneous abscesses caused by either filamentous bacteria (actinomycetoma) or fungi (eumycetoma) found in the soil and enter the body through a break in the skin.
- Mycobacterium avium complex (MAC)** Consists of *Mycobacterium avium* and *Mycobacterium intracellulare*; previously the most common systemic bacterial infection in patients with acquired immunodeficiency syndrome (AIDS) and recently has been associated with pediatric lymphadenitis.
- Mycobacterium tuberculosis complex (MTBC)** Organisms that cause the disease known as *tuberculosis*. Eleven closely related organisms are grouped together to form the *Mycobacterium tuberculosis* complex that includes *M. tuberculosis*, *M. bovis*, *M. africanum*, *M. canettii*, and *M. microti*.

mycolic acids Complex branched-chain fatty acids with large numbers of carbon atoms; components of the *Mycobacterium tuberculosis* cell wall.

mycosis (pl. mycoses) Disease caused by fungi.

myonecrosis Necrosis of the muscle. Synonymous with *gangrene*.

N

nanobiotechnology (nanotechnology) Use of nanotechnology (sometimes called *nanobiotechnology* when used for biological purposes) in molecular diagnostics; also called *nanomolecular diagnostics*. Although there are different definitions of nanotechnology, it is useful to consider it as a technology that uses atomic and/or molecular properties to build structures starting at the molecular level, at the nanometer scale (a nanometer is a billionth of a meter).

narrow spectrum In antimicrobial activity, a limited range of activity of an antimicrobial agent.

National Fire Protection Association (NFPA) hazard rating diamond The NFPA 704 system uses a diamond-shaped diagram of symbols and numbers to indicate the degree of hazard associated with a particular chemical or material. These diamond-shaped symbols are placed on containers of chemicals or materials to identify the degree of hazard associated with the chemical or material.

National Nosocomial Infection Surveillance System (NNISS) Federal system whose goal is to monitor the incidence of healthcare-associated (nosocomial) infections and their associated risk factors and pathogens at the national level, correlating data from multiple health care settings across the United States.

necrotizing fasciitis (NF) Rapidly progressing and frequently life-threatening soft tissue infection; an infectious gangrene typically caused by several different types of bacteria such as group A streptococci.

negative predictive value (NPV) See *predictive value*.

nested polymerase chain reaction (nested PCR) Sensitive PCR technique that uses two PCR assays. The first assay produces PCR amplicon that is then used as template in the second PCR assay.

neutropenia Abnormally reduced concentration or number of neutrophils in the bloodstream.

new drug application (NDA) A request from a drug sponsor to the U.S. Food and Drug Administration (FDA) for approval to market a new drug. The NDA includes information for the FDA to determine if the drug is proven safe and effective for human use before being marketed.

nitrate reduction test Bacteriologic test determining an organism's ability to form nitrite or nitrogen gas by reducing nitrate.

o-nitrophenyl- β -D-galactopyranoside (ONPG) Chromogenic substrate that is initially colorless but is cleaved by β -galactosidase, producing the yellow compound o-nitrophenyl; this test helps to determine if an isolate is a true nonlactose fermenter.

nodular lymphangitis Disorder characterized by inflammatory nodules that occur along lymphatic vessels that drain an area of primary skin infection (also called *lymphocutaneous syndrome*).

nomenclature Devising or choosing names for organisms.

nonchromogenic Refers to *Mycobacterium* spp., such as *M. tuberculosis*, that do not produce pigmentation.

nonencapsulated Strains of bacteria and yeast that do not produce a capsule.

nonfermentative Bacteria that are unable to use glucose or other carbohydrates in the absence of oxygen.

nongonococcal urethritis (NGU) Infectious condition of the urethra in males that is not caused by gonorrheal infection.

nonlactose fermenter (NLF) See *lactose fermenters*.

nonoxidizers Bacteria that neither oxidize nor ferment glucose or other carbohydrates. They derive their energy from carbon compounds other than carbohydrates.

nonphotochromogenic Refers to characteristic appearance of some *Mycobacterium* spp. in which exposure to light does not stimulate pigment production.

nonporous surface Smooth, unpainted solid surface that limits penetration of liquid.

nonselective media Media that support the growth of most nonfastidious aerobes.

nonsusceptible Reporting category used when there are no "intermediate" or "resistant" interpretive criteria, only a "susceptible" interpretive criterion, and the minimal inhibitory concentration or disk diffusion zone size for classifying the organism as susceptible is not achieved.

nontreponemal antibody tests Tests for syphilis that detect antibodies to nontreponemal antigens. Generally, these tests are used to screen for diseases, which are then confirmed using treponemal antibody tests.

nontuberculous mycobacteria (NTM) Mycobacteria not associated with tuberculosis; some are nonpathogenic, whereas others have been commonly implicated as opportunistic pathogens. They are ubiquitous in the environment.

nontypable *Haemophilus influenzae* (NTHi) Strains of *H. influenzae* that are not encapsulated.

normal biota Microbes normally present in an organ or region of the body; they exist in a symbiotic relationship with the host. May act to help prevent infection. These organisms are isolated from the host in the absence of disease.

Northern blot Procedure that detects RNA with a specific, labeled probe. The RNA is separated by electrophoresis and then transferred to a solid membrane. The probe is labeled and detected by a variety of methods.

nosocomial Of or being a secondary disorder associated with being treated in a hospital but unrelated to the patient's primary condition.

nosocomial bacteremia See *healthcare-associated bacteremia*.

nosocomial infection Infection acquired within 72 hours of a stay in a health care facility.

novobiocin susceptibility Test useful for differentiating novobiocin-resistant *Staphylococcus saprophyticus* from other coagulase-negative staphylococci (sensitive).

nucleic acid hybridization Ability of two single-stranded nucleic acid species to anneal, or bind, to each other and form

a hybrid, or duplex. Nucleic acid molecules hybridize when they are complementary to each other.

nucleic acid sequence-based amplification

(NASBA) Amplification assay that occurs at one temperature that produces transcript from a target nucleic acid. This method uses a pair of primers and reverse transcriptase, RNase H, and T7 RNA polymerase to synthesize many transcript copies from each target nucleic acid sequence.

nucleocapsid Genome of a virus enclosed in a protein coat (the capsid).

nucleoside reverse transcriptase inhibitors (NRTIs) A class of antiviral drugs interfering with the function of the enzyme reverse transcriptase, used to treat retroviral infections.

numeric codes Number generated by a series of biochemical tests in a commercial identification kit that can be compared with numbers in a database to identify an organism.

nutrient media Culture media that are complex; made of extracts of meat or soybeans.

O

O antigen Heat-stable somatic cell antigens of the Enterobacteriaceae, notably identified in *Escherichia coli* and *Salmonella* spp.

obligate aerobe Microorganism that requires oxygen for growth.

obligate anaerobe Microorganism that can live and reproduce only in a strict anaerobic environment (0% oxygen).

obligate intracellular parasite Microorganism or virus unable to replicate independently outside a living cell.

occult (unsuspected) bacteremia Bacteremia not associated with any physical signs or symptoms of severe infection.

O/F (oxidative/fermentative) basal medium Bacteriologic medium used in determining the ability of bacteria to use carbohydrates oxidatively or fermentatively.

Ohara disease Another name for tularemia, which is caused by *Francisella tularensis*.

oligonucleotide Small nucleic acid molecule used as a primer or probe in molecular diagnostic techniques; synthetic, single-stranded, nucleic acids complementary to target sequences.

onychomycosis Infection caused by fungi involving the nails.

opaque Not transparent or translucent; impenetrable to light; not allowing light to pass through.

ophthalmia neonatorum Severe eye infection in infants caused by *Neisseria gonorrhoeae*, acquired during natural (vaginal) delivery.

opportunistic Microorganisms that usually do not produce disease but are capable of causing disease in an individual whose immune system is compromised.

opportunistic Taking advantage of a situation, exploiting weaknesses.

opportunistic infection Disease caused by a microorganism with low virulence that becomes pathogenic in a host with low immunologic resistance.

opportunistic pathogen See **opportunistic**.

opsonin Host molecule (e.g., certain complement proteins and antibodies) that enhances phagocytosis.

opsonization Process whereby microorganisms are changed so they are more easily and readily engulfed by phagocytes and macrophages.

optochin test Test that determines an organism's susceptibility to optochin (ethylhydrocupreine); used to differentiate *Streptococcus pneumoniae* (susceptible) from other α -hemolytic streptococci (resistant).

orbital cellulitis Infection of the orbital tissues.

orf Contagious viral skin disease acquired from infected sheep and goats; characterized by painless vesicles that may progress to red weeping nodules and finally to crusting and healing; caused by the orf virus in the genus *Parapoxvirus*.

organ culture Maintenance or growth of organ fragments.

orthostatic changes Changes that occur while in an erect posture or position.

ORYX The Joint Commission initiative requiring health care organizations to submit performance measurements to be analyzed and compared with those of similar institutions.

osteomyelitis Chronic or acute infection of the bone or bone structures as a result of an infective process.

otitis media Disease that results from infection of the middle ear; characterized by the presence of middle ear inflammation and fluid.

outbreak Occurrence of events, such as infections, that exceeds the normal and expected numbers.

outbreak investigation Epidemiologic investigation of an outbreak.

outcome monitors Measurements of the result of a process.

over-the-counter (OTC) drugs Nonprescription drugs that are considered to be safe and effective for consumers to use without professional supervision, provided the required label directions and warnings are followed.

oxacillin-salt screen plate Agar plate containing 6 $\mu\text{g/mL}$ of oxacillin and 4% NaCl used for detecting oxacillin-resistant *Staphylococcus aureus*.

oxazolidinone Class of azoles with the carbon between the nitrogen and oxygen oxidized to a ketone.

oxidase test Bacteriologic test to determine the presence of the intracellular enzyme cytochrome oxidase, part of the electron transport system.

oxidation Chemical process whereby electrons are donated. In bacteria, oxygen is frequently used as the terminal electron acceptor during glucose oxidation; however, other inorganic molecules can also be used.

oxidizers Bacteria that require molecular oxygen as the final electron acceptor; glucose or carbohydrates are metabolized only in the presence of oxygen.

P

pandemic An epidemic that has spread over several countries or continents, usually affecting a large number of people.

Panton-Valentine leukocidin (PVL) Staphylococcal cytolytic toxin that can act on polymorphonuclear leukocytes.

paradoxical (eagle) effect Related to minimal bactericidal concentration testing; decreased bactericidal activity of an

antimicrobial agent at higher concentrations of antimicrobial agent, as demonstrated by more colonies growing on subcultures at higher concentrations than at lower concentrations.

paraffin bait technique Assay used to recover *Nocardia* spp. and aerobic actinomycetes from contaminated samples; based on the principle that these organisms can use simple carbon sources for nutrition.

parapneumonic effusion (PPE) The filling of the pleural cavity with exudative pleural fluids, often secondary to pneumonia.

parasite Organism that lives in or on and takes its nourishment from another organism (host), while harming that organism. Parasitic diseases include infections by protozoa, helminths, and arthropods.

parasitism Relationship between species (host and organism) in which one of the species (parasite) benefits at the expense of the other (host).

paronychia Inflammation of the folds of the skin bordering the nail beds.

paroxysmal phase Second phase of pertussis characterized by the sudden onset of severe, repetitive coughing followed by a "whoop" as the individual gasps for air, sometimes followed by vomiting.

pasteurization Method of disinfection used mostly in the food industry; eliminates foodborne pathogens and organisms responsible for food spoilage. It is carried out at 72° C for 15 seconds. The main advantage of pasteurization is that treatment at this temperature reduces spoilage of food without affecting its taste.

pathogen Microorganism or virus that causes disease.

pathogenic bacteria See **pathogenic microorganism**.

pathogenic microorganism Organism capable of causing disease.

pathogenicity Ability of a microorganism to cause disease.

patient preoperative skin preparation Fast-acting, broad-spectrum, and persistent antiseptic-containing preparation that significantly reduces the number of microorganisms on intact skin.

pattern recognition receptor Protein capable of recognizing molecules frequently found on pathogens; can trigger host defense against pathogens.

pelvic inflammatory disease (PID) Acute or recurring acute infection of the oviducts and ovaries, with surrounding tissue involvement; includes inflammation of the cervix (cervicitis), uterus (endometritis), fallopian tubes (salpingitis), and ovaries (oophoritis), which can spread to adjacent connective tissue. The most common causes are *Chlamydia trachomatis* and *Neisseria gonorrhoeae*.

penicillin-binding protein (PBP) Transpeptidase enzyme important in bacterial cell wall formation. These proteins have various affinities to the β -lactam antibiotics and play an important role in resistance to these agents when altered.

penicillinase-producing *Neisseria gonorrhoeae* (PPNG) *N. gonorrhoeae* that have a type of penicillin resistance caused by genes located on the plasmids that code for penicillinase (a type of β -lactamase) production.

penicillinase-resistant penicillins Group of antimicrobial agents resistant to hydrolysis by β -lactamase, including oxacillin, methicillin, nafcillin, cloxacillin, and dicloxacillin.

peptidoglycan Unique mucopolysaccharide constituent of the bacterial cell wall. The quantity of this polymer and its location within the cell envelope is different between gram-negative and gram-positive bacteria.

performance improvement (PI) Continuous analysis of processes or procedures and continual implementation of improvements.

perinatal Refers to during labor and delivery of an infant; around the time of delivery.

peripheral chromatin DNA present on the nuclear membrane of some protozoa.

periplasmic flagella Fibrils around which the spirochete flexible cell wall is wound; also known as *axial fibrils*, *axial filaments*, *endoflagella*, and *periplasmic fibrils*; responsible for motility.

persistent Refers to prolonged or extended antimicrobial activity that prevents or inhibits the proliferation or survival of microorganisms after product application.

persister cell Microbial cell that is alive but weakly metabolic; it has the potential to return to an actively growing state.

persisters As related to minimal bactericidal concentration testing, the growth of small numbers (>0.1% of the test inoculum) of colonies from several concentrations of antimicrobial agent above the minimal inhibitory concentration.

personal protective equipment (PPE) Specialized clothing or equipment worn by an employee for protection.

pertussis Acute infectious inflammation of the airways characterized by recurrent bouts of spasmodic coughing, followed by a noisy inspiratory stridor, or "whoop." The infection is caused by *Bordetella pertussis* or *Bordetella parapertussis*.

pertussis toxin (PT) Protein exotoxin of *Bordetella pertussis* that produces a wide variety of responses in vivo. The main activity of pertussis toxin is modification of host proteins by ADP ribosyltransferase, which interferes with signal transduction.

petechiae Red spots or discoloration on the skin caused by minor bleeding underneath the skin. See also **purpura**.

phaeohyphomycosis Term used to define infections caused by fungi that produce dark cell walls from the presence of melanin.

phagocyte Mobile or fixed cell in a multicellular organism that is able to ingest debris. Phagocytes are present as "housekeepers" in all multicellular organisms. Neutrophils, macrophages, and histiocytes are the major human phagocytes.

phagocytosis Process of engulfing or ingesting and digesting foreign particles including bacteria.

pharyngitis Upper respiratory tract infection affecting the pharynx that may be caused by a virus or bacterium; acute bacterial pharyngitis is often caused by *Streptococcus pyogenes* and is characterized by sore throat, malaise, fever, and headache.

phenotype Observable or measurable characteristics of an organism.

pheromone Extracellular molecules passed between bacteria, allowing communication. When pheromones bind to specific receptors on bacteria, gene expression is altered.

- photochromogenic** Characteristic appearance of *Mycobacterium* spp. in which exposure to light stimulates pigment production.
- photochromogens** *Mycobacterium* spp. that produce carotene pigment on exposure to light.
- phylum (pl. phyla)** In biological classification, a subset or category.
- pigment** Coloring matter or substance.
- pilus (pl. pili)** Nonmotile, long, hollow protein tubes that connect two bacterial cells and mediate DNA exchange; also known as *conjugation pili*.
- pinta** Nonvenereal skin disease caused by *Treponema carateum*; found in the tropical regions of Central America and South America.
- planktonic** Free-floating microorganisms.
- plasmid** Extrachromosomal, circular pieces of DNA found in many strains of bacteria. Plasmids often carry virulence genes and antimicrobial resistance genes.
- plasmid profile analysis** Nonamplified typing method that analyzes the plasmid DNA profile from bacterial isolates.
- pleocytosis** Presence of white blood cells in cerebrospinal fluid.
- pleomorphic** Demonstrating a variety of shapes and forms; for a Gram stain, neither distinctly coccoid nor rod-shaped; also used to describe the Gram stain morphology of bacteria that exhibit a combination of cocci, bacilli, coccobacilli, and filamentous forms in a single stained smear.
- pleuropneumonia-like organism (PPLO)** After mycoplasmata were isolated from cows with pleuropneumonia, the first human mycoplasma was isolated and was referred to as a pleuropneumonia-like organism.
- pneumonia** Disease characterized by inflammation of the lungs, typically associated with fever, respiratory symptoms, and the presence of parenchymal involvement detected by physical examination or the presence of infiltrates on chest radiography.
- pneumonic plague** *Yersinia pestis* infection involving primary or secondary infection of the lungs.
- pneumonic tularemia** Pneumonia resulting from inhaling *Francisella tularensis*. This is the form that would most likely occur as a result of a bioterror release of this agent, although inhalation tularemia can occur naturally.
- polyclonal** Mixture of antibodies recognizing different antigens and epitopes with different binding affinities.
- polyclonal antibody** Mixture of antibodies able to bind the same antigen but that recognize different epitopes.
- polymerase chain reaction (PCR)** Molecular method that produces an exponential amount of product from a target nucleic acid sequence. PCR consists of denaturation, primer annealing, and primer extension, and it uses several components, including DNA polymerase, primers, target nucleic acid, a buffer, deoxynucleotides, and a thermal cycler.
- polymicrobial** Refers to the presence of two or more microbial morphotypes; if they are likely pathogens in an infection, the infection is polymicrobial.
- polymicrobial bacteremia** Bacteremia that involves more than one microbial organism.
- polymorphic fungus** Fungus that has both yeast and mold states present when cultured under the same growth conditions.
- polymyxin** Polymyxins B and E (also known as colistin) are antibiotics most effective against gram-negative bacteria. They work by damaging the bacterial cell membrane.
- polyvinyl alcohol (PVA)** Plastic resin often used in stool fixatives to adhere fecal material to a slide before staining.
- Pontiac fever** Mild febrile disease without pulmonary symptoms caused by *Legionella* spp.
- porin** Transmembrane structure made up of proteins large enough to facilitate passive diffusion.
- porphyrin** Intermediate substance formed during the biosynthesis of heme.
- positive predictive value (PPV)** See **predictive value**.
- postanalytic activity** Processes that occur after a sample has been analyzed, such as result review, transcription, or reporting of results.
- postsplenectomy** After removal of the spleen.
- postzone** Phenomenon resulting from an antibody solution that is too dilute to demonstrate agglutination or precipitation; also referred to as *antigen excess*.
- Pott disease** Name given to tuberculosis of the spine.
- preanalytic activity** Processes that occur before a sample is analyzed, such as patient identification and sample collection.
- precipitation** Immunologic reaction between soluble antigens and antibodies forming a visible macromolecular complex that falls out of solution.
- precision** Measure of exactness of a test.
- predictive value** Probability that a positive result (positive predictive value [PPV]) accurately indicates the presence of an analyte or a specific disease or that a negative result (negative predictive value [NPV]) accurately indicates the absence of an analyte or specific disease. Predictive values vary significantly with the prevalence of the disease or analyte unless the test is 100% sensitive (for NPV) or specific (for PPV).
- preseptal cellulitis** Inflammation of the periorbital tissues.
- prevalence** Number of cases of a disease that occur in a given moment in time or during a specific period in a given population.
- preventive maintenance** Procedures performed on instruments and equipment designed to keep them operating at optimal performance and to extend their lifetime.
- primary amebic meningoencephalitis** Infection of the central nervous system caused by the free-living amoeba, *Naegleria fowleri*.
- primary atypical pneumonia** Pneumonia that differs from the typical pneumonia caused by *Streptococcus pneumoniae*; primary refers to the fact that it is not preceded by another infection. Common causes of atypical pneumonia include *Legionella pneumophila*, *Chlamydia pneumoniae*, *Chlamydia psittaci*, and *Mycoplasma pneumoniae*. Atypical pneumonia caused by *Mycoplasma pneumoniae* is also known as walking pneumonia.
- primary bacteremia** Bacteremia that arises from an endovascular source, such as an infected cardiac valve or infected intravenous catheter.
- primary cell culture** Culture started from cells, tissues, or organs taken directly from an organism.
- primary syphilis** First stage of syphilis marked by the development of a chancre and spread of the causative spirochete in the tissues of the body.

primer Small, single-stranded oligonucleotide used in a polymerase chain reaction or other molecular diagnostic method. Primers anneal to target sequences, and DNA polymerase starts the synthesis of new DNA strands from the primers.

primer annealing Second step of a polymerase chain reaction, in which primers anneal to denatured target nucleic acid strands. This hybridization reaction usually occurs at a temperature of 5° C lower than the melting temperature (T_m) of the primers.

primer-dimers Primers that anneal to each other and form hybrids during a polymerase chain reaction or other amplification procedures.

primer extension Third step of a polymerase chain reaction. Once primers have annealed to template nucleic acid, DNA polymerase uses free deoxynucleotides and synthesizes new strands of DNA from the primers.

prion Infectious proteinaceous particle. These agents are known to cause degenerative diseases of the nervous system (transmissible spongiform encephalopathies), such as Creutzfeldt-Jakob disease in humans.

probe Oligonucleotide with an attached label for detection, often a fluorescent chemical. Probes anneal to target sequences in many molecular diagnostic reactions.

probe-mediated stain Relatively simple chemical stain used to make antibody- or nucleotide-mediated identity reactions visible.

process monitor Ongoing data collection that can be used to establish trends or spot problems when trends are disrupted.

proctitis Rectal inflammation that can occur as a primary manifestation of infection following direct inoculation of the rectal mucosa.

proficiency testing Testing of carefully designed, “unknown” samples to evaluate analytic processes.

proglottid One segment of a tapeworm. Each proglottid contains both male and female reproductive organs.

prokaryote Microorganisms that lack a true nucleus and nuclear membrane and organelles.

prostatitis Inflammation in the prostate.

protective antigen One of three proteins that make up the anthrax toxin. Protective antigen is necessary for edema factor and lethal factor to bind to and penetrate host cells.

protein A Cellular component of *Staphylococcus aureus* that can bind immunoglobulin G and prevent phagocytosis.

protein expression Process whereby a gene's DNA sequence is converted into a structure or function of a cell; also called *gene expression*.

proteomics Large-scale analysis of protein expression, often at the cellular level. This method is often used to analyze proteins expressed in various disease states.

prozone Phenomenon resulting from a high concentration of antibodies preventing agglutination or precipitation; also referred to as *antibody excess*.

pseudobacteremia Seen when bacteria are recovered from blood cultures; might be caused by contamination of blood samples during phlebotomy, leading to false-positive results.

pseudo-germ tube Tubelike projection from a blastoconidium or spore, with a constriction at its base.

pseudohypha (pl. pseudohyphae) Chain of elongated fungal cells with constrictions at points of attachment resembling true hyphae.

pseudomembranous colitis See *Clostridioides difficile*-associated disease.

pseudomonad Gram-negative, nonfermentative, oxidase-positive bacillus, possessing polar flagella; found in most aquatic environments; not usually part of the normal human biota.

psychrophile Organism that grows best at cold temperatures (optimal growth at 10° to 20° C).

public health The scientific discipline that pertains to protecting the safety and health of people and their communities.

pulsed-field gel electrophoresis (PFGE) Commonly used strain-typing method. A restriction enzyme is used to digest chromosomal DNA, and the resulting fragments are separated in an agarose gel in a pulsed electric field. The strains show unique banding patterns.

purified protein derivative (PPD) Diagnostic skin test for tuberculosis containing proteins from *Mycobacterium tuberculosis*.

purpura Purplish discoloration that appears under the skin, caused by bleeding underneath the skin. Small spots are called *petechiae*; large areas are referred to as *ecchymoses*.

purpura fulminans Skin manifestation of disseminated intravascular coagulation (DIC) that is classically associated with meningococcemia, but has also been associated with *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Haemophilus influenzae* bloodstream infections. It is characterized by rapidly developing skin hemorrhage and necrosis and peripheral gangrene accompanied by shock syndrome.

purulence Seen grossly as pus, consisting of neutrophils, protein, and necrotic debris.

pyelonephritis Inflammation that involves the kidneys.

pyocyanin Water-soluble blue pigment, characteristic of *Pseudomonas aeruginosa*. When combined with the fluorescein pigment of *P. aeruginosa*, it forms blue-green colonies on a variety of solid media.

pyoderma Skin infection characterized by the appearance of pus and necrosis in tissues.

pyogenic streptococci See *Streptococcus pyogenes*.

pyoverdin Fluorescein pigment of members of the *Pseudomonas* fluorescent group. Fluorescein can be seen with ultraviolet light. When combined with the pyocyanin (blue) pigment of *P. aeruginosa*, a blue-green colony results.

pyrosequencing Sequencing by synthesis technique that does not require labeled nucleotides or primers and also does not require a postreaction electrophoresis step. It is a rapid sequencing technique that generates approximately 20 to 50 base sequences per primer, so this technique is best used for short sequences. Pyrosequencing uses the enzymes DNA polymerase, ATP sulfurylase, luciferase, and apyrase and the substrates adenosine 5'-phosphosulfate (APS) and luciferin.

pyrrolidonyl- α -naphthylamide (PYR) hydrolysis Test used for the presumptive identification of group A streptococci (positive) and enterococci (positive). The substrate is hydrolyzed to β -naphthylamine by the enzyme pyrrolidonyl arylamidase.

pyuria Presence of white blood cells (leukocytes) in the urine; more than 8 to 10 leukocytes/mm³ indicates significant pyuria.

Q

Q fever See **query fever**.

Q probes External peer comparison program sponsored by the College of American Pathologists that addresses process, outcome, and structure-oriented quality assurance issues.

QRNG Fluoroquinolone-resistant *Neisseria gonorrhoeae*.

quality assurance (QA) A process that involves monitoring all components of a system or procedure (preanalytical, analytical, and postanalytical) and implementing changes when suboptimal performance is identified, involves taking proactive measures to ensure high-quality patient care.

quality control (QC) System for detecting and correcting analytic errors by establishing performance limits and ensuring the maintenance of proper standards, especially by periodic random inspection of the product.

quantitative isolation Technique in which a measured amount of specimen is inoculated to an agar plate to determine the quantity of microbes in the specimen.

query fever Original name of Q fever, caused by *Coxiella burnetii*.

quinolone Class of broad-spectrum antimicrobial that acts by inhibiting the bacterial enzyme DNA gyrase or topoisomerase IV enzyme, thereby inhibiting DNA replication and killing the organism.

quorum sensing Process whereby bacteria communicate by means of extracellular molecules called *pheromones*.

quorum-sensing inhibitor (QSI) Molecule that can interfere with the quorum sensing system of bacteria. They have been used in an attempt to disrupt biofilms.

R

radial immunodiffusion (RID) Precipitation method with antibody evenly distributed in agarose and antigen added to wells. As antigen diffuses, it forms a concentration gradient. At some point it forms a zone of equivalence with the antibody and a precipitate forms. The precipitant ring is proportional to antigen concentration.

radioimmunoassay (RIA) Immunoassay that uses radioactive isotopes to detect antigen-antibody complexes in vitro; rarely used today in clinical laboratories.

random amplified polymorphic DNA (RAPD) Amplified strain-typing procedure that uses random sequence primers that anneal to random chromosomal DNA sequences of the strain of interest; a PCR assay is used to amplify DNA, and strains have unique patterns of fragments.

rapid diagnostic test (RDT) An easy-to-use test that provides quick results, usually in 20 minutes or less; many are point-of-care tests.

rapid plasma reagin (RPR) test Nontreponemal serologic test for syphilis.

RASE Term used to describe prescription drug products that are "recognized as safe and effective."

reagin antibody (RB) Antibody produced during *Treponema pallidum* infection against nontreponemal antigens. Immunoglobulin E antibodies cause a type 1 hypersensitivity reaction; also referred to as *reagin*.

real-time polymerase chain reaction (PCR) Commonly used detection method for PCR amplicons. A probe or fluorescent dye is used for detection. The real-time PCR platform analyzes the accumulation of fluorescence after every PCR cycle so the results can be observed on a computer screen in real time. Thus PCR and detection are coupled from the same tube.

reemerging pathogens Microbial pathogens, once thought to be eliminated or greatly reduced in numbers, that are seen once again or potentially seen.

Regan-Lowe (RL) transport medium Recommended transport medium for suspected *Bordetella pertussis* when overnight or several-day transport is required; contains charcoal (half-strength from charcoal horse blood agar isolation media), 10% horse blood, and 40 mg/L cephalaxin.

Reiter syndrome Disorder that causes urethritis, conjunctivitis, polyarthritides, and mucocutaneous lesions; in adults it is believed to be caused by *Chlamydia trachomatis*.

relapsing fever Can be tickborne (endemic relapsing fever) or louseborne (epidemic relapsing fever); caused by *Borrelia* spp. Relapsing fever is best prevented by control of exposure to the arthropod vectors.

relebactam A β -lactamase inhibitor approved for use in combination with imipenem/cilastatin.

repetitive palindromic extragenic element polymerase chain reaction (Rep-PCR) Form of strain typing using primers complementary for repetitive palindromic sequences that occur throughout chromosomes. PCR is used to amplify DNA between the palindromic sequences. Strains have unique fragment patterns.

resident microbial biota Microorganisms usually found at a particular body site of healthy individuals and that remain at the site for long periods or indefinitely.

resistant strain In therapeutic terms, these strains are not inhibited by the usual systemic concentrations of the antimicrobial agent with normal dosage schedules or fall in the range in which specific microbial resistance mechanisms are likely and clinical efficacy has not been reliable in treatment studies.

respiration The efficient, energy-generating process in which molecular oxygen is the final electron acceptor; also called *oxidation*.

respiratory burst Release of reactive oxygen species (superoxide radical and hydrogen peroxide) from different types of cells. It usually denotes the release of these chemicals from immune cells (e.g., neutrophils, macrophages) as they come into contact with different bacteria or fungi.

restriction enzyme Enzyme that cuts DNA at specific deoxyribonucleotide sequences. Many unique restriction enzymes are commercially available. They are used in various molecular techniques, such as Southern blotting; also called *restriction endonuclease*.

reticulate body (RB) Metabolically active noninfectious form of *Chlamydia*.

retinitis Inflammation of the retina.

reverse passive agglutination test Agglutination immunoassay in which antibodies are attached via the Fc portion of the antibody to a carrier particle such as latex.

reverse transcription–polymerase chain reaction (RT-PCR) Type of PCR that uses reverse transcriptase to produce cDNA copies of transcript. The cDNA is then used in a standard PCR assay using specific primers. RT-PCR is used to assay for RNA viruses and analyze transcript.

rhabditiform larva Feeding but noninfective larval stage; this stage hatches from the egg.

rheumatic fever A sequela of *Streptococcus pyogenes* pharyngitis characterized by fever and inflammation of the heart, joints, blood vessels, and subcutaneous tissues.

rheumatoid factor (RF) Autoantibody, usually immunoglobulin M, directed against abnormal immunoglobulin G antibodies.

rhinocerebral mucormycosis Infection of the sinuses, nasal passages, oral cavity, and brain caused by saprophytic fungi. It usually affects individuals with diabetes and those who are immunocompromised. The infection can rapidly result in death.

rhizoid Rootlike hypha.

ribonuclease H (RNase H) Ribonuclease that degrades RNA in DNA-RNA hybrids.

ribotyping Method that detects rRNA restriction fragment length polymorphism patterns by Southern blotting. It displays excellent reproducibility and discriminatory power because the genes that code for rRNA are conserved in different species of organisms and appear in conserved positions of a species chromosome.

ricin Derived from the seeds of castor oil plant, a potent biological toxin that inhibits protein synthesis.

risk group Categorization for infectious agents based on hazardous characteristics and relative risk.

Ritter disease Disorder also known as *staphylococcal scalded skin syndrome*.

river blindness Disease caused by *Onchocerca volvulus*; also called *onchocerciasis*.

Rocky Mountain spotted fever (RMSF) Most severe of the rickettsial infections; the most common in the United States. Humans acquire the infection by tick bites; caused by *Rickettsia rickettsii*.

rolling circle amplification (RCA) An isothermal enzymatic amplification strategy to synthesize ultralong single-stranded DNA.

rotavirus Member of the family Reoviridae that infects cells of the villi of the small intestine, leading to epithelial atrophy and proliferation of cells with secretory capacity. This may decrease the absorptive capacity of the bowel, contributing to diarrhea. Rotaviruses are the major cause of diarrhea in children younger than 5 years of age.

S

safety data sheet (SDS) See **material safety data sheet**.

salpingitis Inflammation of the fallopian tubes.

Sanger sequencing DNA sequencing method utilizing the random incorporation of chain-terminating dideoxynucleotides by DNA polymerase during in vitro DNA replication followed by electrophoresis.

saprobe Environmental fungus that derives nutrients from dead organic material; generally nonpathogenic for humans.

satellitism Small colonies of bacteria growing around another colony; the small colonies derive an essential nutrient secreted by the other colony; phenomenon exhibited by some *Haemophilus* spp. on sheep blood agar.

scalded skin syndrome (SSS) Toxin-mediated exfoliative dermatitis associated with *Staphylococcus aureus*, superficially resembling a burn injury.

scarlet fever Disease characterized by a diffuse red rash that appears on the upper chest and spreads to the trunk and extremities; caused by strains of *Streptococcus pyogenes* that produce an erythrogenic toxin.

schizogony Asexual life cycle of the Apicomplexa. In malaria, it is characterized by splitting of the nucleus into multiple segments and the formation of merozoites.

schizont Parasitic form producing merozoites during schizogony. In malaria, it is part of the erythrocytic asexual life cycle.

Schüffner stippling Malarial pigment characterized as tiny red staining dots in red blood cells infected with *Plasmodium vivax* or *P. ovale*.

scleritis Inflammation of the sclera, the white outer layer of the eyeball.

scolex Anterior end of a tapeworm that contains structures such as suckers or hooklets used for attachment to the host.

scombroid Form of food poisoning from ingestion of heat-stable toxins produced by bacteria in contaminated fish—often tuna, mackerel, or yellow jack.

Scorpion primer Used with a real-time polymerase chain reaction (PCR) assay. A Scorpion primer is a hairpin loop structure with a fluorophore on the 5' end and a quencher on the 3' end. Also attached to the 3' end is a small primer sequence specific for the target of interest. The primer anneals to target nucleic acid, and primer extension occurs. Denaturation dissociates the PCR product and the Scorpion primer. A portion of the primer is complementary to the PCR product and anneals to it, physically separating the fluorophore from the quencher, and an increase in fluorescence is observed.

scotochromogenic Refers to *Mycobacterium* spp. producing pigment in a light or dark growth environment.

secondary bacteremia Bacteremia that arises from an infected extravascular source such as the lung in patients with pneumonia.

secondary syphilis Second stage of syphilis that appears 2 to 6 months after primary infection; marked by lesions, especially in the skin, but also in organs and tissues; lasts from 3 to 12 weeks.

select agent Biological agent or toxin deemed by the U.S. Department of Health and Human Services to have the potential to pose a serious threat to public health and safety and to animal health and animal products.

select biological agent Microbial agents classified by the Centers for Disease Control and Prevention as potential agents of bioterrorism because of their dissemination potential and ability to cause disease and/or death in humans, animals, and plants.

selective media Media that support the growth of one type or one group of microbes but not of another type.

selective reporting Reporting of results for certain antimicrobial agents based on defined criteria such as organism identification, body site, and overall susceptibility profile following testing of a clinical isolate. Secondary (broader-spectrum, more costly, more toxic) agents are only reported if primary agents are resistant or if they offer significant clinical advantages for the particular isolate and patient.

sentinel laboratories Part of the Laboratory Response Network; composed of most of the hospital-based microbiology laboratories.

sepsis Systemic response to bacterial infection.

septic shock Sepsis accompanied by refractory hypotension.

septicemia Bloodstream infection. See **sepsis**.

sequencing Determining the primary structure of an unbranched biopolymer in genetics and biochemistry. Sequencing results in a symbolic linear depiction, known as a *sequence*, that succinctly summarizes much of the atomic level structure of the sequenced molecule. DNA sequencing is the process of determining the nucleotide order of a given DNA fragment.

seroconversion Demonstration of detectable antibodies to an immunogen, such as an infectious agent or vaccine.

serology Study of serum or, more specifically, the use of immunologic assays to detect antibodies for the purpose of diagnosing an infectious disease.

serotype Antigenic constituency of an organism.

serotyping Example of phenotypic testing used with biochemical testing for identifying or classifying different strains of bacteria within a species. Serotyping uses antibodies to detect specific antigens on the surface of bacteria; also called *serogrouping*.

serum bactericidal test (SBT) Method for determining the highest dilution or titer of a patient's serum that is inhibitory to the patient's own infecting bacterium and the highest dilution or titer bactericidal to the patient's own infecting bacterial isolate.

sessile Microorganisms attached to a solid surface, usually found in a community of cells called a *biofilm*.

sexual reproduction Union of a male and a female cell to produce a zygote.

Shiga toxin (Stx) One of two toxins produced by *Shigella* and enterohemorrhagic *Escherichia coli* strains, toxic to African green monkey kidney (vero) cells.

Shiga-toxin producing *Escherichia coli* Strain of *E. coli* that produces Shiga toxin 1 and/or Shiga toxin 2, resulting in gastroenteritis.

shock Serious, life-threatening medical condition in which insufficient blood flow reaches the body tissues.

simple stains Chemical stains that are water- or alcohol-based that can be used directly on a fixed or air-dried sample

without additional preparation or complex steps. Gram, Wright, and acridine orange are simple stains.

sinusitis Disease that results from infection of one or more of the paranasal sinuses.

Six Sigma (6σ) A tool for process improvement that designates how often mistakes are likely to occur in a process or procedure and represents the number of errors per million opportunities—the higher the Sigma, the fewer the number of errors. A Sigma score of six is the highest level that can be achieved.

skipped wells As related to broth dilution minimal inhibitory concentration testing, refers to growth at higher concentrations and no growth at one or more of the lower concentrations of antimicrobial agent in the series of concentrations tested.

small colony variants Rare, fastidious strains of staphylococci requiring CO₂, hemin, or other complex nutrient for growth; grow on media containing blood, forming colonies about 10% of the size of wild-type strains after incubation for at least 48 hours.

smooth Characterization of some edges of colonies; having an even and regular surface or consistency.

sodium polyanethol sulfonate (SPS) Anticoagulant used in collection of microbiology specimens. In addition to preventing clot formation, it is anticomplementary and antiphagocytic.

Southern blot Hybridization procedure in which chromosomal DNA is digested with a restriction enzyme and the fragments are separated by agarose gel electrophoresis. A specific, labeled probe is then used to detect target DNA.

species In microbiology (biology), it is the basic unit of biodiversity. In classifying organisms, it is assigned a two-part name in Latin; the genus is listed first, followed by a specific species name.

spirochetes Slender, flexuous, helically shaped, unicellular bacteria ranging from 0.1 to 0.5 μm wide and from 5 to 20 μm long, with one or more complete turns in the helix.

sporangiophore Hypha stalk upon which a sporangium develops; the stalk may be branched or unbranched.

sporangiospore Asexual spore produced in a sporangium.

sporangium (pl. sporangia) Closed sac-like structure containing asexual spores.

spore In fungi, a unit of asexual reproduction that may be adapted for dispersal and survival, often for extended periods, in unfavorable conditions. In bacteria, spores are a means of surviving harsh conditions; they are not a means of reproduction. In bacteria, spores appear as highly refractile bodies in the cell. They are visualized microscopically as unstained areas in the cell when using traditional bacterial stains (Gram). May be stained with specific spore stains.

sporocidal Refers to a substance or product that kills spores.

sporoblast Structure within an immature oocyst that ultimately develops into a sporocyst.

sporocyst Structure within the oocyst that contains the sporozoites.

sporogony Sexual life cycle of malaria that takes place in the gut of the mosquito; results in the production of sporozoites, the infective stage for humans.

sporozoite Elongated cell that develops within an oocyst. In malaria, it is the stage transmitted to humans when the mosquito takes a blood meal. In other members of the Apicomplexa, it is contained within the oocyst that is passed in the feces.

standard precautions Infection control precautions that assume that all patients are potentially infectious; practices are implemented to prevent contact with blood and body fluids.

staphylocoagulase See coagulase.

staphylococcal enterotoxins Small-molecular-weight polypeptides belonging to the bacterial superantigen family.

staphylococcal scalded skin syndrome See scalded skin syndrome.

static Term indicating that a substance inhibits the growth of an organism but that on removal the organism might grow again.

sterile pyuria Presence of 10 white blood cells per high-power field seen in centrifuged urine samples without any uropathogens recovered from urine cultures.

sterilization Refers to the destruction of all forms of life, including bacterial spores.

strain Variant of a plant, bacterium, or virus.

strand displacement amplification (SDA) An isothermal assay that can detect trace amounts of DNA or RNA.

streamers Growth of an organism in liquid media, represented by vines and puffballs.

streptococcal pyrogenic exotoxin Toxin produced by some strains of *Streptococcus pyogenes*; can result in scarlet fever.

streptogramin Antibiotic mixture of two structurally distinct compounds, type A and type B, that are separately bacteriostatic but bactericidal in appropriate ratios. These antibiotics act at the level of translation inhibition through binding to the bacterial ribosome. Quinupristin and dalfopristin are both streptogramins.

streptolysin O (SLO) Oxygen-labile hemolysin produced by *Streptococcus pyogenes* responsible for hemolysis on sheep blood agar plates incubated anaerobically.

streptolysin S Streptococcal hemolytic exotoxin that is oxygen-stable, lyses leukocytes, and is nonimmunogenic. The hemolysis seen around colonies that have been incubated aerobically is caused by streptolysin S.

string of pearls Description of the microscopic appearance of *Bacillus anthracis* after short-term exposure to penicillin. The presence of large spherical organisms in chains is useful for a presumptive identification.

stringency Strictness of binding of complementary single-stranded nucleic acid molecules modulated by altering the hybridization conditions.

stye An infection involving one or more of the small glands near the base of an eyelash, usually caused by bacteria.

suboptimal specimen Specimen that is not properly selected, collected, or transported and will lead to misleading results in a microbiology workup.

sulbactam A β -lactamase inhibitor used with ceftriaxone.

sulfamethoxazole (SMZ) Antimicrobial that blocks the step leading to the formation of 7,8-dihydropteroate by competitively inhibiting the binding of the structural

analogue *p*-aminobenzoic acid with dihydropteroate synthase.

sulfide-indole-motility medium (SIM) Bacteriologic medium used to determine whether an organism is motile and has the ability to produce H_2S and form indole from tryptophan.

sulfur granules Masses of filamentous organisms mixed with inflammatory debris that may appear yellow or orange seen in certain mycetomas.

superoxide anion Oxygen free radical, O_2^- , toxic to cells.

superoxide dismutase Enzyme composed of metal-containing proteins; converts superoxide radicals into less toxic agents.

suppurative Forming or discharging pus.

surgical hand scrub Antiseptic-containing preparation that significantly reduces the number of microorganisms on intact skin; it is broad-spectrum, fast-acting, and persistent.

surgical site infection (SSI) Infection that occurs at a surgical site (incision).

surveillance Ongoing systematic collection of data; analysis and interpretation of details surrounding a disease or event.

surveillance culture Testing of selected patients or environmental sources to identify the source of infectious agents.

susceptible In therapeutic terms, implies that a bacterial strain tested is inhibited or killed by an antimicrobial agent and the infection it is causing may be appropriately treated with the dosage of antimicrobial agent recommended for that type of infection and infecting species.

swarming Refers to a hazy blanket of growth on the surface that extends well beyond the streak lines.

swimmer's itch Dermatitis caused by the larvae of certain schistosomes of birds and mammals that may penetrate the human skin.

SYBR Green Dye that binds to nucleic acids; fluoresces green after exposure to ultraviolet light. SYBR Green I is used to stain DNA, and SYBR Green II is used to stain RNA.

Sydenham chorea A neurological disorder linked to *Streptococcus pyogenes* infection.

symbionts Organisms that share a relationship; typically at least one member of the pair benefits from the relationship.

symbiosis Relationship (interaction) between species (host and organism) in which typically at least one benefits from the relationship.

synanamorph Two or more different fungi that reproduce asexually (anamorphs) but have been linked to the same sexual fungus (telomorph).

syncytia Giant multinucleated cells formed from cell fusion as a result of virus infection.

synergism Occurs when the antimicrobial activity of a combination of antimicrobial agents is greater than the activity of the individual agents alone.

syphilis Multistage sexually transmitted disease caused by *Treponema pallidum* subsp. *pallidum*.

syphilitic chancre Initial lesion of syphilis that is painless and nonsuppurative but infectious; its appearance signals primary syphilis. The chancre appears at the site of inoculation, usually the genitalia.

systemic inflammatory response syndrome

(SIRS) Inflammatory state affecting the whole body related to sepsis; SIRS comprises a spectrum of increasingly severe conditions ranging from sepsis to severe sepsis to septic shock.

T

T-helper cells Cells that express CD4 and a T-cell receptor on their surfaces and respond to antigen presentation by antigen-presenting cells.

T-strain mycoplasma Original name given to the *Ureaplasma* spp. because they produce tiny colonies compared with the *Mycoplasma* spp.

tache noire Literally “black spot”; characteristic lesion that can form when *Rickettsia conorii* or *Orientia tsutsugamushi* organisms infect humans; formed at the arthropod vector bite site.

tachyzoite Motile, replicating intracellular stage of *Toxoplasma gondii*.

target Nucleic acid species studied in molecular diagnostics assays. The target is single-stranded and complementary to primers and/or probes.

targeted surveillance Surveillance of specific, preidentified events of concern or importance.

taxa Term that denotes categories of organisms.

taxonomy Orderly classification and grouping of organisms into taxa or categories.

tazobactam A β -lactamase inhibitor used with piperacillin.

teleomorph Form of a fungus that reproduces sexually.

temperate Phage DNA that becomes incorporated into the bacterial genome, where it is replicated along with the bacterial chromosomal DNA.

template Target nucleic acid for molecular diagnostics assays.

tertiary syphilis Third stage of syphilis; develops after the disappearance of the secondary symptoms, marked by ulcers in and gummas under the skin and commonly by involvement of the skeletal, cardiovascular, and nervous systems.

test validation Ongoing process providing information that a test is performing correctly.

tetanospasmin Neurotoxin that interferes with the release of neurotransmitters, blocking inhibitor impulses, leading to unopposed muscle contraction and spasm, the characteristic signs and symptoms of tetanus produced by *Clostridium tetani*.

tetanus Disease that acts on the central nervous system; characterized by muscular contractions See **tetanospasmin**.

tetracycline Broad-spectrum antibiotic produced by the *Streptomyces* spp., indicated for treatment of various bacterial infections. It inhibits cell growth through inhibition of translation by binding to the 30S ribosomal subunit and preventing the aminoacyl tRNA from binding to the A site of the ribosome.

The Joint Commission (TJC) Health care accrediting organization whose mission is to improve the safety and quality of care provided to the public.

thermal cycler Programmable instrument that cycles temperatures for PCR assays.

thermophiles Bacteria that grow best at high temperatures (optimal growth at 50° to 60° C).

thiosulfate citrate bile salts sucrose (TCBS) agar Selective medium used for isolation of *Vibrio* spp. Sucrose-fermenting species are yellow; nonsucrose-fermenting organisms are green.

thrush Yeast infection occurring in the oral mucosa, generally found in patients with a cell-mediated immune deficiency.

tigecycline The first drug in the glycylcycline class of antibiotics, related to tetracycline.

Tier 1 agent Designation applied to biological agents and toxins that present the greatest risk of deliberate misuse with significant potential for mass casualties or devastating effect to the economy, critical infrastructure, or public confidence, and pose a severe threat to public health and safety.

time-kill assay Method for measuring the rate of killing of a bacterial isolate by an antimicrobial agent by examining the number of viable bacteria remaining at various intervals after exposure to the agent.

tinea Term used to denote superficial fungal diseases of various parts of the body; also called *ringworm*.

tissue culture Maintenance or growth of complex tissue.

T_m See **melting temperature**.

tolerance As related to minimal bactericidal concentration (MBC) testing, the lack of bactericidal activity at several concentrations above the minimal inhibitory concentration (MIC), often defined as an MBC/MIC ratio of 32:1 or higher.

total quality management (TQM) A management framework based on the belief that an organization can build long-term success by having all its members, from low-level workers to its highest ranking administrators, focus on improving quality and thus delivering customer satisfaction.

total surveillance Surveillance of all events in a health care setting.

toxic epidermal necrolysis (TEN) Clinical manifestation of a disorder with multiple causes, often a drug or chemical reaction; may resemble scalded skin syndrome.

toxic megacolon Life-threatening complication of intestinal conditions characterized by a very inflated colon, abdominal distention, fever, pain, and shock.

toxic shock syndrome (TSS) Potentially fatal multisystem disease caused by toxins, primarily TSST-1, produced by *Staphylococcus aureus*.

toxic shock syndrome toxin-1 (TSST-1) Exotoxin acting as a superantigen; usually associated with toxic shock syndrome.

tracheal cytotoxin Virulence factor of certain *Bordetella* spp. that contributes to pathogenesis by causing ciliostasis, inhibiting DNA synthesis, and promoting cell death.

trachoma Chronic severe eye infection associated with specific serovars (A, B, Ba, and C) of *Chlamydia trachomatis*.

trailing As related to broth dilution minimal inhibitory concentration testing, growth at lower concentrations followed by one or more wells or tubes that show greatly reduced growth in the form of a small button or light haze.

transcript Messenger RNA, the expressed product of a gene.

transcription Process whereby a template DNA strand is copied into a functional RNA sequence, resulting in mature mRNA or structural RNA.

transcription-mediated amplification (TMA) Amplification assay similar to nucleic acid sequence–based amplification.

transduction Transfer of bacterial genes by a bacteriophage (bacterial virus) from one cell to another.

transformation Uptake and incorporation of naked DNA into a bacterial cell.

transient bacteremia Bacteria in the bloodstream sometimes occurring after procedural manipulation of a particular body site colonized by indigenous biota.

transient microbiota Microorganisms that reside at body sites for short periods, sometimes for days or weeks. Not usually part of the established microbiota.

transillumination Passing of bright light through the bottom of the plate to determine whether the organism is hemolytic. This technique can be also used on clear media (e.g., MacConkey), to see slight differences in the color of nonlactose-fermenting bacilli.

translation As in genetics, the process of using a DNA sequence (gene) to make proteins.

translucent Permitting light to pass through but diffusing it so objects on the opposite side are not clearly visible.

transmission-based precautions Extra steps are needed to prevent the spread of an infectious agent when a patient is known or suspected to be infected or colonized with an infectious agent.

transparent Having the property of transmitting light rays through a substance so objects situated beyond or behind can be seen distinctly.

transport medium Liquid or semi-solid medium meant to preserve and maintain the integrity of infectious agents in a clinical specimen for the period between specimen collection and laboratory processing.

transposon (Tn) Segment of DNA that can become integrated at many different sites along a chromosome, especially a segment of bacterial DNA that can be translocated as a whole.

traveler's diarrhea Acute diarrheal illness generally acquired when travelers ingest contaminated food or water; often caused by enterotoxigenic *Escherichia coli*; also known as *turista*.

treponemal antibody tests Tests for syphilis that detect specific antibodies to treponemal antigens used to confirm a nontreponemal antibody screening test.

trichomoniasis Extremely common sexually transmitted infection; common manifestation of vaginitis. *Trichomonas vaginalis* is the causative agent of trichomoniasis.

trimethoprim (TMP) An antimicrobial agent that interferes with folic acid metabolism; It is often used with sulfamethoxazole.

triple sugar iron (TSI) agar Bacteriologic medium that aids in the determination of carbohydrate fermentation (glucose, lactose, and sucrose) and H₂S formation.

trophozoite Feeding, motile, noninfective form of a protozoan. This form replicates in the host and is responsible for causing damage.

true pathogen Microorganism capable of producing disease in immunocompetent and immunocompromised individuals; sometimes referred to as *overt pathogen*.

trypomastigote Life-cycle stage found in humans characteristic of blood and tissue flagellates; long, spindle-shaped organism with a flagellum, undulating membrane, prominent nucleus, and kinetoplast.

tuberculous meningitis Meningitis or inflammation of the meninges from an infection caused by *Mycobacterium tuberculosis*.

tularemia Disease caused by the bacterium *Francisella tularensis*.

tumbling motility Characteristic end-over-end motility of *Listeria* spp.

turbidity Cloudiness of liquid media caused by growth of microorganisms.

turista See **traveler's diarrhea**.

type B gastritis Type of chronic gastritis usually associated with *Helicobacter pylori* infection.

U

ulceroglandular tularemia Most common form of tularemia; characterized by a skin ulcer at the site of entry and swollen region lymph nodes..

umbilicate Depressed center, concave.

umbonate Raised or bulging center, convex.

undulant fever Synonym for *brucellosis*; rising and falling fevers.

undulating membrane A cytoplasmic membrane associated with some flagellates that extends out like a fin of the outer edge of the cell, moving in a wavelike fashion.

uracil-N-glycosylase (UNG) Enzyme that prevents replication of DNA strands synthesized with uracil instead of thymine. UNG is sometimes used as a contamination prevention measure.

urea breath test Rapid diagnostic procedure used to identify infections by *Helicobacter pylori*, a bacterium implicated in gastritis, gastric ulcers, and peptic ulcer disease; patients are given an oral dose of radioactive urea. In patients with *H. pylori* infection, radioactive carbon dioxide can be detected in the breath.

urease test Bacteriologic test to determine an organism's ability to break down urea with the enzyme urease.

ureteritis Inflammation of one or both ureters, ducts that carry urine from the kidneys to the bladder.

urethritis Inflammation of the urethra.

urinary tract infection (UTI) Infection occurring in or associated with the urinary tract.

usual (indigenous) microbiota Microorganisms usually found at body sites without causing disease; certain species may produce disease, given the opportunity, or when the host's immune system is weakened.

uveitis Inflammation of the iris, ciliary body, and choroidal tissues.

V

V factor (nicotinamide adenine dinucleotide [NAD]) Growth factor that some *Haemophilus* spp. require in media for growth; also known as *nicotinamide adenosine dinucleotide*.

vaccinia virus Virus strain used to vaccinate humans against smallpox.

vasculitis Widespread inflammation of small blood vessels.

vancomycin agar screen plate Brain-heart infusion agar plate containing 6 µg/mL of vancomycin; used for detection of vancomycin-resistant enterococci, vancomycin-intermediate *Staphylococcus aureus*, and vancomycin-resistant *S. aureus*.

vancomycin-intermediate *Staphylococcus aureus* (VISA) *S. aureus* isolates that show reduced susceptibility levels to vancomycin and fall in the intermediate range of 8 to 16 µg/mL.

vancomycin-resistant enterococci (VRE) Enterococci that have vancomycin minimal inhibitory concentration in the resistant range ≥ 32 µg/mL.

vancomycin-resistant *Staphylococcus aureus* (VRSA) *S. aureus* organisms that have vancomycin minimal inhibitory concentration in the resistant range ≥ 32 µg/mL.

variola major Severe form of smallpox, with approximately 30% mortality.

variola minor Milder form of smallpox, with approximately 1% mortality.

vector Organism responsible for transmitting parasite from infected host to noninfected host.

Venereal Disease Research Laboratory (VDRL)

test Nontreponemal antigen test commonly used for the diagnosis of syphilis, named after the Venereal Disease Research Laboratory where the test was developed.

ventilator-associated pneumonia (VAP) Pneumonia whose cause has been associated with a ventilator device, such as an endotracheal tube or a tracheotomy.

verotoxin See Shiga toxin.

vesicles Liquid-filled sacs.

Vi antigen See K antigen.

viremia Presence of viruses in the blood.

virion Complete virus particle.

virucidal Antimicrobial that inactivates viruses.

virulence Degree of pathology caused by an organism. The extent of the virulence is usually correlated with the ability of the pathogen to multiply within the host; may be affected by other factors; the disease-evoking power of a microorganism.

Voges-Proskauer (VP) test See methyl red–Voges-Proskauer (MRVP) test.

vulvovaginal candidiasis Symptomatic vaginitis usually caused by infection with the yeast *Candida*.

W

Waterhouse-Friderichsen syndrome Complication of *Neisseria meningitidis* infection involving hemorrhage of the adrenal glands; characterized by a sudden onset of fever, cyanosis, petechial hemorrhages of the skin and mucous membranes, and coma.

Weil disease Severe systemic form of leptospirosis that includes renal failure, hepatic failure, and intravascular disease; may result in death.

Weil syndrome Synonym for icteric leptospirosis.

Whipple disease Rare intestinal disease caused by *Tropheryma whippelii*; characterized by severe intestinal malabsorption.

whooping cough See pertussis.

wool sorter's disease Name given to inhalation (pulmonary) anthrax describing anthrax disease associated with occupational exposure to *Bacillus anthracis* spores as a result of handling contaminated animal products.

work practice controls Alterations in the manner in which a task is performed to reduce the likelihood of exposure to infectious agents.

X

X factor Growth factor that some *Haemophilus* spp. require in media for growth; also known as *hemin* or *hematin*.

Y

yaws Nonvenereal spirochetal disease of the tropics resembling syphilis; caused by *Treponema pallidum* subsp. *pertenue*.

yeast Fungus that reproduces by budding.

Z

zeta potential Electrical or charge potential on cells. As in immunoassays, erythrocytes have a negative charge and will repel each other. In order to exhibit hemagglutination, antibody-antigen interaction must overcome the zeta potential.

Ziehl-Neelsen stain Stain often used in procedures for acid-fast staining. It is a carbolfuchsin method that involves the application of heat.

Ziemann dots Malarial pigment characterized as tiny, red-staining dots, smaller than Schüffner stippling, in red blood cells infected with *Plasmodium malariae*.

zone of equivalence Portion of a precipitin or agglutination curve when antibody and antigen concentrations are optimal for lattice formation.

zone of inhibition Zone related to disk diffusion testing; a clear area of no growth surrounding an antimicrobial disk following overnight incubation; results from diffusion of the antimicrobial molecules into the agar and growth inhibition of the test bacterium.

zoonosis (pl. zoonoses) Disease that humans acquire from exposure to infected animals or products made from infected animals.

zoonotic Pertains to diseases that can be transmitted from animals to humans.

 oxacillin resistance in, 287
 protein A and, 312
 significance of, 311*t*
 skin and wound infections with, 313
 TSST-1 and, 311
 vancomycin resistance in, 288–289
 virulence factors of, 310–312, 312*t*
- Staphylococcus delphini*, 309
- Staphylococcus epidermidis*, 28, 311*t*, 314, 929, 929*t*, 930*t*
- Staphylococcus hyicus*, 309, 311*t*
- Staphylococcus intermedius*, 309, 311*t*
- Staphylococcus lugdunensis*, 309, 311*t*, 314
- Staphylococcus lutrae*, 309
- Staphylococcus pseudintermedius*, 309, 315*b*
- Staphylococcus saprophyticus*, 311*t*, 314, 929–930, 929*b*, 930*t*
- Staphylococcus schleiferi*, 309
- Staphylococcus sciuri*, 311*t*
- Staphylococcus simulans*, 311*t*
- Steer’s replicator, 279*f*

- Stenotrophomonas maltophilia*, 485–486
 clinical infections from, 485–486
 identifying characteristics of, 486
- Sterilization, 66
 biofilms and, 68
 compatibility of disinfectants in, 68–69
 concentration of disinfecting agent and, 68
 contact time and, 68
 degree of killing in, factors influencing, 67–69
 disinfection *versus*, 66–67
 methods of, 69–71
 chemical, 70
 physical, 69–70
 nature of surface for, 68
 organic material and, presence of, 68
 pH and, 68
 temperature and, 68
- Stock cultures, use of, in quality control, 115
- Stock solutions, antimicrobial, 277
- Stomach, microorganism in, 29
- Stool
 Mycobacterium spp. and, 585
 specimen collection from, 126
- Stop codons, 22
- Strain typing and identification, 241–243
- Strains, 6
- Strand displacement amplification (SDA), 239
- Strawberry cervix, 951, 951f
- Streamers, 177–178, 178f, 778
- Streptobacillus moniliformis*, isolation of, 135t
- Streptococcal pyrogenic exotoxins, 328
- Streptococcal toxic shock syndrome (TSS), 329
- Streptococcus agalactiae*, 180f, 330–332, 892
 antigenic structure of, 330
 classification of, 327t
 clinical infections of, 330–332
 laboratory diagnosis of, 332, 332f
 virulence factors of, 330
- Streptococcus anginosus*
 characteristics of, 336t
 classification of, 327t
- Streptococcus bovis*
 characteristics of, 336t
 classification of, 327t
- Streptococcus dysgalactiae*, classification of, 327t
- Streptococcus equi*, classification of, 327t
- Streptococcus mitis*
 characteristics of, 336t
 classification of, 327t
- Streptococcus mutans*
 characteristics of, 336t
 classification of, 327t
- Streptococcus pneumoniae*, 36t, 333–334
 antigenic structure of, 333
 antimicrobial resistance and, 334
 bacterial meningitis and, 891–892
 classification of, 327t
 clinical infections of, 333
 colony morphology of, 179f
 differentiation of, 179f
 laboratory diagnosis of, 334, 334f
 penicillins for, 284–285, 285f
 susceptibility testing and, 284–285, 285f
 virulence factors of, 333
- Streptococcus pyogenes*, 36t, 38t, 180f, 327–330
 antigenic structure of, 327
 bacterial pharyngitis and, 328, 328b
 classification of, 327t
 clinical infections from, 328–329
 laboratory diagnosis of, 329–330
 necrotizing fasciitis and, 328–329
 poststreptococcal sequelae and, 329
 pyoderma infections and, 328
 serologic testing for, 208
 toxic shock syndrome and, 329
 virulence factors of, 327–328
- Streptococcus salivarius*
 characteristics of, 336t
 classification of, 327t
- Streptococcus* spp.
 biochemical identification of, 330, 331t, 340–344, 341f, 342f
 cell wall structure of, 325–326, 326f
 classification of, 327t
 clinical infections of, 337
 clinically significant, 326–340
 general characteristics of, 325–326, 325f
 group A, testing of throat samples for, 118
 hemolysis and, 326, 326b, 326t
 hemolytic patterns and, 340
 laboratory diagnosis of, 337–338
 Lancefield classification system and, 340
 noncultural identification of, 344–345
 immunoassays and, 344
 slide agglutination test and, 344, 344f
 susceptibility testing and, 345
 nucleic acid probe assays and, 344–345
 phenotype and biochemical characteristics of, 337–338, 337t
 physiologic characteristics of, 340
 virulence factors of, 337
- Streptococcus*-like organisms, 338–340
 Abiotrophia and *Granulicatella* spp. and, 338
 Aerococcus spp. and, 338
 clinically significant, 326–340
 Dolosicoccus and *Globicatella* spp. and, 338–339
 Dolosigranulum spp. and, 339
 Facklamia spp. and, 339
 Gemella spp. and, 339
 Lactococcus spp. and, 339
 Leuconostoc spp. and, 339, 339f
 Pediococcus spp. and, 339–340
 Vagococcus spp. and, 340
- Streptogramins, 253t–254t
- Streptolysin O (SLO), 327
- Streptolysin S, 328
- Streptomyces* spp., 362–363, 363t
- Streptomycin, 253t–254t, 575
- Strict anaerobes, 15
- Stridor, 803
- Stringency, 229
- Strobila, 687f
- Strongyloides* infection, 859
- Strongyloides stercoralis*, 693t, 694, 697–699, 698f, 699f, 700f
 cancer patients and, 978
- Subculturing, 171–172
- Subcutaneous layer, of skin, 833, 834f
- Subcutaneous mycoses, 602
 agents of, 607–610
- Subcutaneous phaeohyphomycosis, 608–609, 609b
- Suboptimal specimens, 130
- Substrata, 778
- Subterminal spores, 501, 502f
- Sudan ebolavirus (SUDV), 733, 765
- Sugars, 185
- Sulbactam, 263
- Sulfamethoxazole (SMZ), 258
 Streptococcus spp. and, 331t
- Sulfide-indole-motility (SIM) agar, 191
- Sulfonamides, 253t–254t
- Sulfur granules, 361, 362f
- Superficial candidiasis, 834–836
- Superficial mycoses, agents of, 603–604
- Superoxide anion, 498
- Superoxide dismutase, 498
- Suppurative lymph nodes, 394
- Suprapubic aspirate, specimen collection from, 125t–126t
- Suprapubic aspiration, 933, 937
- Sure-Vue Mono test kit, 209f
- Surface proteins, bacteria, 5f
- Surgical hand scrub, 75, 76t, 77
- Surgical site infections (SSIs), 52, 53t
- Surgical therapy, 529
- Surveillance
 cultures, 54
 infection control and, 53–55, 54b
 baseline data, 54
 data gathering, 54–55
 definition of, 53–54
 general or targeted, 54
- Susceptibility testing
 Aeromonas spp. and, 466–467, 467b
 of agents of bioterrorism, 286
 anaerobes and, 286–287, 527–529, 529t
 options, 528–529
 problems in, 528–529
 antifungal, 635–636
 antimicrobial, 271, 272b, 319–322
 automated, 293–295
 procedures in, 272–273
 QC for, 295–298, 296t, 297t, 298t
 reasons and indications for, 273–274
 selecting, 298–299
 special, 299–300, 299b–300b, 300t
 traditional, 275–282
 battery selection for, 274, 274b
 body site in, 273
 Bordetella and, 414–416
 Borrelia burgdorferi and, 538
 Borrelia recurrentis and, 537
 Campylobacter spp. and, 471
 dilution and, 276–279
 disk diffusion testing and, 279–282, 279f
 Enterococcus spp. and, 289–290, 289f
 Etest and, 286–287
 Haemophilus influenzae and, 285
 Haemophilus parainfluenzae and, 285
 Helicobacter pylori and, 286
 host status in, 273
 inoculum preparation and standardization for, 275–276
 Klebsiella pneumoniae carbapenemase, 291
 Legionella and, 411

Susceptibility testing (*Continued*)

- for leptospires, 536, 536b
- MBC test and, 299–300, 300t
- McFarland turbidity standards and, 275–276
- MRSA and, 287
- of *Mycobacterium tuberculosis*, 594–595
- Mycoplasma* spp. and, 567
- Neisseria gonorrhoeae*, *Neisseria meningitidis* and, 286
- oxacillin and, 277t, 287–288, 288b, 288f
- presence of other bacteria and quality of specimen in, 273
- rapid, 299
- reporting results of, 274–275
- SBT and, 300t, 302
- selection of agents for, 274–275, 275b
- synergy tests and, 300t, 302, 302b
- test performance of, 280–282
- time-kill assays and, 300t, 301–302
- Treponema pallidum* and, 541
- Ureaplasma* spp. and, 567
- UTIs, 937–940
- vancomycin resistance in *Staphylococcus aureus* and, 288–289
- Vibrio* spp. and, 463
- Svedberg, Theodor, 7
- Svedberg units, 7
- Swabs, 506, 506f, 549
 - from smears, 141, 141f
- Swarming, 175f

 Urease test, 191–192, 192f, 194t, 632
 anaerobe identification and, 515
 Mycobacterium spp. and, 593, 593f
 yeast and, 634
 Urethra, specimen collection from, 125t–126t
 Urethral specimens, of parasites, 644
 Urethritis, 546–547, 782, 924, 925b, 945b
 causes of, 931t, 945
 clinical manifestations of, 946–947, 947f
 epidemiology of, 945, 946f
 gonococcal, 945
 laboratory diagnosis of, 947–948, 947f
 nongonococcal, 546–547, 562, 945
 overview of, 945–948
 treatment of, 948
 Urinary system, 923, 926t
 anatomy of, 923f
 Urinary tract infections (UTIs), 274, 922, 922b–923b, 923b, 924t, 925b, 926f, 939b
 age and, 925–927
 antibiograms, 938–940
 bacteremia and, 910
 bladder catheterization and, 927
 causative agents of, 929–931, 929b, 929t, 931t
 causes of, 928–931, 931t
 clinical signs and symptoms of, 927–928, 928f
 coagulase-negative staphylococci causing, 930t
 colony counts, historical background for, 931–932
 cultures for, 936, 938f, 939t
 epidemiology and risk factors for, 925–927, 926b
 Escherichia coli causing, 422
 fungi and, 930–931, 931b, 935
 gram-negative bacilli and, 929

- Urinary tract infections (UTIs) (*Continued*)
 gram-positive bacilli and, 930
 gram-positive cocci and, 929–930
 interpretation of results, 937
 laboratory diagnosis of, 931–934
 microbial detection of, 934–935
 pathogenesis of, 928–929
 pregnancy and, 927
Pseudomonas fluorescens, *Pseudomonas putida* and, 483
 renal transplantation and, 927
 sexually transmitted infections, 927
 specimen collection for, 932–934
Staphylococcus aureus and, 310
 susceptibility testing and, 937–940
- Urine
 additives to, 934
 comparative parameters for, 924*t*
Mycobacterium spp. and, 584–585
 screening methods for
 automated, 935, 936*t*
 manual, 934–935, 935*b*, 935*t*
 specimen collection from, 125*t*–126*t*, 126
 transport of, 932–933
 volume of, 933
- Urine antigen test, 411
- Urine specimens, of parasites, 644
- Urogenital diseases, *Chlamydia trachomatis* and, 546–547
- Urogenital parasites, specimens examined for, 643–644
- Urogenital specimens, mycotic sample collection of, 628
- Uropathogenic *Escherichia coli*, 422, 423*t*
- V**
- V factor, 391–392, 396, 396*f*
